In appendicitis a second operation is often necessary to relieve obstruction or break up adhesions which were the result of the incomplete primary operation. In many of these cases, as in others, the complications are so great and extensive that the operator, not having the knowledge and skill, or lacking courage, abandons the procedure with the entirely too common apology, "inoperative," "hopeless." The freeing of visceral adhesions in primary operations is rare, and for this reason very much work is to be gone over again and with all the difficulties aggravated tenfold. Too many operators are content with the simple removal of a growth, without correcting the fixation or pathological conditions about it. A partially adherent bladder, if not freed, will remain a perpetual source of annoyance. Bands of adhesions about the ileum, if not freed, form the post-operative obstruction we see so commonly reported. The removal of remaining and irritated material, careful trimming of all ragged, fringy adhesions, clearing away of all débris and clot, and well placed drainage at the seat of oozing, will favor a perfect cure.

It is sometimes necessary to retie old pedicles when portions of original cyst or tumor remain in the pedicle, and cut or scrape with a sharp knife the dirty seat of dead ligatures, and stitch healthy peritoneum over these parts.

Unfortunately, too many poor women continue to suffer from post-operative lesions; they are told to have patience, that the symptoms will vanish. Very frequently there is opposition on the part of the physician to reopening and correcting the mischief; some look upon visceral adhesions as necessarily fatal. A few of us do not consider an operation complete until all visceral adhesions have been carefully freed and repaired and left in as normal a condition as possible; after the repair of viscera for the removal of growths placing all viscera in physiological relation. A number of prominent operators remove tumors without examining surrounding parts. When we hear of a case operated upon two or three times by the same operator, we have no difficulty in forming an estimate of his

surgical ability. We know that in his primary operation, in his second and probably third venture, he left something behind he should have removed at first; all through he was doing incomplete work. While the author fully realizes that too much surgery in extremely debilitated patients will kill just as surely as none at all, yet wrong methods of procedure must always have much to do with the necessity for repeating operation.

Our courage should be strong. We want great masters in our science to grow up among us. Frequently some one of our medical or surgical brothers comes running out of the bushes crying, "I have found something." It is usually a germ, an antitoxin, or a new method; as a rule they amount to nothing.

There are few more potent factors in the mid-direction of our surgical efforts than the importunities of our subjects for immediate bodily relief or comfort. This idea has, the author is sure, more influence with the younger practitioners anxious to please and show their resources. This brings up the important fact that a clear judgment as to methods for the eventual welfare of the patient must be uninfluenced by any consideration of present desire. Of course, we would not bar any harmless comfort, since we aim always at a favorable condition of mind; but there can be no doubt that even a quick sympathy will urge the physician to hesitancy or a rash performance. He must be far above any effects of the patient's talk.

As we age, as our experiences crowd upon us, our science, with all its mysteries, becomes a clearer science; and as more weighty grow our responsibilities, the more enlarged our conceptions of duty, the more keenly do we feel the issues we carry in our hands.

#### EXCISION OF ILIAC ANEURISM.

DOLLINGER (*Pest. Med.-Chir. Presse*, 1897, No. 49) showed, four months after the operation, a man of thirty-two, from whom he had removed an aneurism of the right external iliac artery. The patient had had a pulsating swelling in the right groin for some two years, but could trace it to no traumatic cause. The aneurism was situated at the right external iliac artery into the femoral, and was two and a half inches long by one and a half broad; it had grown very rapidly during the past few months. The patient could not stand the pain of digital compression, so that an operation became necessary.

The Hunterian operation was regarded as risky, as the artery could not retract and there might be severe secondary hemorrhage; and the recent statistics of Delbet induced the author to adopt a modernized form of Antyllus's procedure. The prognosis in the matter of liability to gangrene was most favorable, as it was found before the operation that a collateral circulation already existed. An incision was made parallel to Poupart's ligament, the aneurism pushed forwards and the peritoneum upwards, and the artery was tied nearly an inch above the former. The narrow femoral, which was only of the size of the temporal, was next ligatured, and the sac dissected out and removed. The limb at first went pale, but under massage it became yellowish, and finally of the normal color. The patient made an uninterrupted recovery, and when shown had good use in his limbs.—*British Medical Journal*, April 2, 1898.

#### COXA VARA.

DE QUERVIAN (*Semaine Médicale*, Jan. 29, 1898) has collected the literature of a little known deformity of the hip described recently under the name of "coxa vara," from analogy with genu varum. It consists essentially in a downward bending of the neck of the femur, the head being lower than the head of the great trochanter. Several varieties have been described: (a) Congenital (rare). (b) Infantile (rickety coxa vara): (1) simple bending downwards of the neck (Kocher's coxa adducta); (2) bending of the neck downwards and backwards. (c) Coxa vara adolescentium: (1) Kocher's coxa adducta; (2) downward and backward displacement of the neck with rotation of the head on its long axis; (3) elevation of the trochanter and inward rotation. (d) Coxa vara of adults (the only observed case due to osteomalacia).

Frequency: This deformity, at any rate the rickety variety and that found in adolescents where there are generally no signs of rickets, is much more common than is generally thought.

Sex: Males more often affected than females.

Etiology: In infancy, rickets; in adolescence, probably late rickets as in genu valgum, where the other signs have disappeared, or rarely cretinism, or possibly juvenile osteomalacia. Predisposing causes are inflammatory processes in the neck of the femur, either tuberculous or osteomyelitic, and also

employments necessitating much standing or lifting weights. Frequently an injury precedes it or aggravates the already existing condition. It is usually unilateral.

Symptoms: The onset is insidious pain, often felt chiefly in the knee, being the first symptom; then limping, with perhaps difficulty in kneeling and sitting. The pain is worst while the process is developing, but while pain usually decreases the joint stiffness often increases progressively.

Physical signs: Projection of the trochanteric region with a depression between great trochanter and glutei; thigh muscles usually atrophied; abduction of hip always limited, with tendency to adduction. Where the downward bending of the neck is combined with a backward displacement and rotation of the head the signs are more marked. The limb is then rotated outwards and adducted, while internal rotation and often flexion are impossible. The trochanter is above Nelaton's line in all cases. Prognosis depends on age. Before five years the deformity is due to rickets, and may disappear spontaneously; after this age a functional improvement only is possible through adaptation to the new conditions.

Diagnosis: From (1) forward dislocation of the head; (2) recent fracture of the neck, if after an injury there is great aggravation of the pain; (3) from old fracture with resulting deformity; (4) separation of the epiphysis; (5) congenital dislocation; (6) tuberculous disease. In the latter case the chief point is that though in early hip disease there may be slight external rotation, this is accompanied by abduction and flexion instead of adduction without flexion.

Treatment: (1) Of any constitutional disease such as rickets. (2) Absolute rest in bed with permanent extension relieves the pain and improves the movements and helps spontaneous straightening in rickety cases. (3) When the case has gone on for some time and the difficulty of walking, etc., is great, some form of osteotomy (the author prefers linear of the neck) must be performed.—*British Medical Journal*, April 2, 1898.

#### BOTTINI'S OPERATION FOR HYPERTROPHY OF THE PROSTATE.

FREUDENBURG (*Berl. Klin. Woch.*, No. 46, 1897) reports a case of complete retention from prostatic hypertrophy in a patient aged sixty-three, which was entirely removed by galvano-caustic incision of the enlarged

gland after the failure of bilateral castration. The urine, which after the first operation had remained turbid, became quite clear after the second, and the patient is now able to relieve his bladder regularly without using a catheter. This case, it is stated, shows that Bottini's operation acts directly by removing the obstacle to the discharge of urine, and not, as has been suggested, by merely destroying the orifices of the ejaculatory ducts, and the ganglia and nerves which extend to the vesiculæ seminales and vasa deferentia. It is of practical importance also, as it suggests a doubt whether it be advisable to perform castration for relief of urinary retention before an attempt has been made to overcome this result of prostatic enlargement by galvanic incision of the gland.—*British Medical Journal*, March 26, 1898.

#### INJURIES OF THE URETER.

Mr. HENRY MORRIS, the Hunterian lecturer at the Royal College of Physicians of England for this year, has recently published in the *Edinburgh Medical Journal* an exhaustive paper on "Injuries of the Ureter." This paper has a close connection with the Hunterian Lectures (abstracts of which we shall shortly publish), their general title being the "Origin and Progress of Renal Surgery." He confines his remarks to subparietal injuries, excluding penetrating wound, of which there is only one undoubted case on record, and obstetrical injuries which come for consideration under ureteral fistulæ. Twenty-three cases are to be found in surgical literature published as injuries of the ureter, but of these only eleven can be considered as injuries of the ureter proper, the remaining twelve being cases of rupture of the renal pelvis or of the renal substance opening calyces and giving rise to extravasation of urine. These eleven cases fall into three classes: verified cases of rupture of the ureter (two cases), with extraperitoneal extravasation and tumor in one and with intraperitoneal extravasation but no tumor in the other; probable rupture of the ureter with extravasation (four cases); and contracted ureter with hydronephrosis, etc., possibly due to ureteral injury (five cases). The causes comprise forcible compression of the body between two hard objects, kicks from horses, the passage of a wheel over the trunk, falling down stairs, the bursting of a shell, and a violent jerk in jumping from a horse.

When the ureter is torn through and the

peritoneum remains intact (as it usually does) a tumor will sooner or later be formed by the accumulation of urine in the retro-peritoneal tissue; but if the ureter be not torn through, but contused or otherwise injured, a tumor will in course of time be formed consisting of one or other of the varieties of obstructed kidney, namely, renal abscess, pyonephrosis, hydronephrosis, or polycystic kidney. If the ureter be at once completely obstructed by blood-clot and remain so, atrophy of the kidney will probably result.

In two of the eleven cases a communication was formed between the cavity containing urine and the large bowel. The symptoms of rupture of the ureter are not characteristic; for a time there may be only pain and tenderness, and no indication in the urine of any injury. Hematuria may be entirely absent, or it may be slight and transient. If the ureter alone be ruptured the hematuria is not likely to be considerable or prolonged, but slight hematuria or even no hematuria may occur in renal as well as in ureteral injuries. If one or both kidneys are seriously injured there may be incomplete or complete suppression of urine. Pain and tenderness at the part injured is a common immediate symptom. The pain may be referred to the loin, the front of the abdomen, the umbilicus, or to the middle of Poupart's ligament. This pain may pass off in a day or two and the patient remain quite free until fresh pain is caused by the development of a tumor. Transient collapse and vomiting may occur. In some of these cases there was ecchymosis over the loin, the abdomen, and the inguinal region.

If the patient survives a swelling will form due to a retro-peritoneal collection of urine, or urine and blood, or to one or other of the changes which supervene in the kidney. If of the former variety, the swelling forms early, in a few days or weeks, but if of the latter only in many weeks, months, or even years. The tumor is usually well defined, palpable from the loin and front of the abdomen, and may extend from the thorax into the false pelvis. As soon as the fluid in the retro-peritoneal space decomposes inflammation, suppuration or sloughing occurs with corresponding symptoms, viz., increased pain, redness of the skin of the loin, edema of the abdominal wall, pyrexia, furred tongue, anorexia, and constipation or diarrhea. Fluid drawn from the tumor before the occurrence of suppuration has the characters more or less pronounced of urine, but it is generally alka-

line, of low specific gravity (1008 to 1010), and contains very little urea and probably a little albumen and blood; when septic changes have occurred it contains pus. On the other hand, when the tumor is formed by the kidney itself and a long time after the accident, the case will probably be considered as one of the forms of renal enlargement and not at all in relation to injury of the ureter.

The ideal treatment for rupture is immediate suture or anastomosis of the ureter, but this is usually impossible as the diagnosis cannot be made until some time after the injury. Puncture of the retro-peritoneal cyst has been adopted, but with uncertain result. A free incision in the ilio-costal space will secure evacuation of the extravasated fluid. If the ureter is not completely torn across the experience afforded by operations for calculi affords grounds for the expectation of the cicatrization of the wound and the re-establishment of the ureteral channel. The incision may be prolonged towards Poupart's ligament, passing a finger's breadth in front of the anterior superior iliac spine. It will no doubt be difficult to trace the ureter, but the search may be facilitated by remembering that it is carried forwards with the detached peritoneum, to which it is attached about half an inch or more external to where the peritoneum is tied down to the spinal column. But in none of the recorded cases has the site of the injury been ascertained and suture accomplished. If the rupture cannot be found the incision in the loin and drainage will give the most favorable opportunity for repair; there is abundant evidence that surgical wounds of the kidney, pelvis and ureter will heal without sutures. If the ureter be completely torn asunder its ends should be anastomosed; if this cannot be done a permanent fistula in the loin is to be expected, which will save the integrity of the kidney. When suppuration has occurred its consequences may necessitate nephrectomy.—*The Lancet*, April 2, 1898.

#### CONTUSION OF THE ABDOMEN.

NIMIER (*Archives de Médecine et de Pharmacie Militaires*, March, 1898), writing on this topic, formulates the question, Should the surgeon practise immediate laparotomy on every patient who has been kicked in the belly by a horse? He answers this by a guarded negative. Seven times in the last year he has temporized and all his patients

have recovered. He has collected 307 cases of abdominal contusion by horse-kick treated expectantly, and of this number 215 recovered and 92 died. Of 38 cases in which intervention was practised, 26 died; 12 recovered. In but three of these latter could the operation be considered imperative. In one successful case there were no intestinal lesions, nor was there any blood in the peritoneal cavity, hence it is probable recovery would have taken place without operation. Four successful laparotomies were practised twelve to fifteen hours after accident, three from fifteen to twenty-four hours, two the second day after, and one after a time not definitely designated. As to laparotomies followed by death, three were performed in less than twelve hours from the time of accident, twelve in from fifteen to twenty-five hours, nine more than twenty-four hours after, and two after a time not noted.

A very brief consideration of the above figures should suggest the thought that the general adoption of a rule to the effect that every person kicked in the stomach by a horse should be at once cut does not seem to be wise. Unfortunately, there is no absolutely characteristic sign which would lead us to be certain that the intestine has been torn. It is usually necessary to wait for peritoneal reaction and symptoms of general intoxication before the presence of this accident can be determined. The amount of shock is by no means an index as to the presence or absence of visceral lesion. The same can be said of quite a severe localized pain. It is usually necessary, then, for the surgeon to hold himself prepared for operation. In the meantime the patient must be carefully watched.

The author recognizes four morbid types consecutive to rupture of the peritoneum following horse-kick. In the first type peritoneal symptoms are prominent. Pain becomes more severe and generalized, the belly becomes distended, the muscular walls rigid; then nausea, bilious vomiting, hiccough, constipation, retention of urine, or anuria. The autopsy shows purulent peritonitis with false membranes. Among the general symptoms may be noted peritoneal fascies, hyperpyrexia, rapid and small pulse, frequent and superficial respiration, rapid emaciation, delirium, collapse, and death. The second type is like the first as far as peritoneal reaction is concerned, but in place of hyperpyrexia there is subnormal temperature, consequently a disassociation of the temperature and pulse.

the latter, together with respiration, being rapid. Intense vascular congestion is found at the autopsy, and ecchymosis with the false membrane. In the third and fourth types peritoneal symptoms are comparatively inconspicuous. Those of general intoxication, however, are pronounced. In one type there is pyrexia, and in the other subnormal temperature. They represent a peritoneo-intestinal septicemia. At the autopsy of a case of septicemia characterized by high temperature, false membranes and purulo-sanguinolent liquid were found in the peritoneal cavity. In the second type of septicemia with subnormal temperature neither adhesions nor pus are found, but a small quantity of reddish, sometimes fetid, liquid.

It is safe to adopt as a principle that on the first symptoms of peritoneal reaction or of general intoxication, laparotomy should be practised. As to the practical application of the author's study he holds that every patient kicked in the belly should be at once transported to the hospital. There, after having taken a careful history of the accident, the surgeon should institute an expectant treatment based upon the limiting of shock and the indices of intestinal lesion. The patient should be immobilized in bed, should have heat applied to him, should receive proper applications for pain, and should be put on an absolute diet. He is watched carefully, and every half hour the temperature and respiration should be recorded, together with a note of the general and local symptoms. As soon as the symptoms of peritoneal reaction or general infection become distinctly marked intervention should be practised.

---

*EXTERNAL URETHROTOMY: SOME OF THE INDICATIONS FOR AND METHODS OF OPERATING.*

The *Pennsylvania Medical Journal* for March, 1898, contains an article with this title, contributed by J. D. THOMAS. He completes his paper as follows:

When there is no obstruction to the introduction of a grooved staff the operation is simple and can be quickly done. An incision beginning back of the scrotum and carried in the line of the raphe to within one-half or three-fourths inch of the anus is made. The skin, superficial and deep layers of fasciæ are first incised, when the accelerator urinæ muscle comes into view. This is a rather fleshy muscle, and when it is reached the groove of

the sound should be located with the nail of the left index-finger, and a knife with a double edge at the point should be thrust into the groove with precision. If the knife does not enter the groove in the staff on the first attempt the fibers of the muscle fall together, so that when the following attempts are made to strike the groove the muscle is minced to that degree. After the point of the knife has entered the staff the incision in the urethra can be enlarged to the extent desired by sweeping the point of the knife along the groove in the staff. If it is desired to introduce the finger into the bladder, a grooved director is passed along the staff into the bladder, the staff being now removed, and the floor of the urethra, in the direction of the bladder, incised, with the director as a guide. If necessary, the bladder may be then flushed with any solution desired.

If the operation is undertaken for a tight stricture, a filiform is first passed into the bladder, then over this a tunneled instrument is passed until it presses against the face of the stricture. The incision in the perineum is now made on to the end of the tunneled instrument, when the black filiform comes into view. The incision follows this as a guide until the stricture is split. The grooved director may now be introduced and the operation proceeded with as indicated above.

Sometimes cases are met with where it is impossible to introduce an instrument into the bladder to serve as a guide. This condition is encountered where the urethra has been lacerated or torn off by traumatism; occasionally from stricture due to gonorrhea. In these cases a sound as large as can be introduced is passed down against the stricture and an incision made through the perineum on to this. A better instrument for this purpose is Wheelhouse's staff. The incision is made into the groove on the end of this instrument, which is then turned around, *in situ*, and the upper end of the wound is caught with the little knob on the distal end, which is at an angle with the shaft. A ligature—artery clips will answer—is now placed on either side at the bottom of the wound, and by making traction on these three the finding of the urethra is facilitated. Where the stricture is due to gonorrhea the continuity of the urethra is not disturbed, and the urethral canal may be traced along toward the bladder. When the inability to pass a filiform guide is due to a rupture of the urethra, or when it is torn off, the distal portion of the urethra is very difficult to find. If

it cannot be found readily, rather than make mince-meat of the perineal tissues and subject the patient to prolonged anesthesia, it is better surgery—and the proceedings can be conducted with precision—to do a suprapubic cystotomy and find the posterior portion of the urethra by retro-catheterization. With one sound passed through the meatus externus, the other through the bladder and meatus internus, the torn urethra is brought into apposition without destructive dissection, when it may be sutured if desired, and an opening made into the bladder through the perineum farther back.

The author wishes here to mention a little wrinkle in operating upon the urethra that has served him to excellent purpose on five occasions. On these occasions he encountered strictures in the penile urethra that would admit nothing larger than a filiform. Then on attempting to pass the smallest tunneled cutting instrument they were found so dense that they could not be penetrated. In attempting to force the instrument along the guide, the penile organ would be crowded down into the subpubic space or doubled upon itself. To overcome this trouble he drew the distal end of the filiform out through the perineal wound already made and tied to this a silk thread, then withdrew the filiform by the meatus, bringing with it the thread, so that one end of the thread projected from the meatus, the other from the wound. Taking hold of these ends he resorted to an up-and-down sawing motion, while an assistant made pressure on the under surface of the organ immediately opposite the seat of stricture. After enlarging the caliber of the stricture in that way, the instrument was slipped along the thread, which now served as a guide.

Every author with whom the writer is acquainted recommends that, after this operation, a drainage tube be introduced through the wound into the bladder and that a packing of iodoform gauze be placed around this; or that a soft-rubber catheter be passed into the bladder *per urethram* and tied in. In his estimation this is not good treatment. In the first place, it is painful for the patient; in the second place, it requires a good deal of care on the part of the attendant; in the third place, the drainage tube soon becomes filthy and the packing becomes saturated with urine, which undergoes decomposition, thus necessitating frequent change, with its accompanying pain; and in the fourth place, when the catheter is tied in, a urethri-

tis is surely set up. The writer's practise is, that when the operation is over, he places the patient in bed with a rubber urinal under him, the urethra is irrigated three times a day with Thiersch's solution, and the perineal wound is kept clean and is irrigated with a bichloride of mercury solution 1:4000. The urine for the first few days is continually passing through the wound, and thus we have an automatic flushing of the wound with an aseptic and antiseptic solution, which the urine is. The patient is absolutely comfortable; his convalescence is rapid, for these patients sometimes leave the hospital perfectly sound in two weeks. The only discomfort he experiences is when—twice a week—the sound is passed. The author never puts in a drainage tube unless it is to control hemorrhage, which seldom occurs from the operation *per se*, or when he wants to keep the wound from healing too rapidly, or when the urethra has been sutured.

#### GENU RECURVATUM.

GERARDT MARCHANT (*Revue d'Orthopédie*, No. 1, 1898) publishes a rare case of acquired genu recurvatum. The patient, a lad aged seventeen, had been treated when five years old for an abscess in the right thigh. After this had been opened, there was during two years a continuous discharge from two openings, which, when finally closed, were replaced each by a permanent scar—one superficial and mobile, on the front of the thigh, the other depressed and fixed to bone, on the outer surface. The deformity which developed slowly after the complete healing of the abscess was characterized by marked hyperextension of the right leg, which formed with the thigh a retiring angle of 160°. When the patient was recumbent on his back, the only portion of the right lower limb which touched the couch was the popliteal region. The patella was elevated far above the knee, and fixed in front of the thigh. The muscles of the thigh were much wasted. The leg was fixed, and the affected limb was shorter than its fellow by a little more than two inches. On careful examination of the thigh the author made out a stiff and tense cord, evidently formed by the lower half of the quadriceps muscle, stretched from the middle of the thigh to the patella. It was assumed that the previous suppurative affection—probably of osteomyelitic origin—had resulted in abnormal adhesion of the extensor muscles to the front of the femur,

and that the portion of the quadriceps intervening between two fixed parts, namely, its insertion below and its adhesion to the bone above, had been prevented from keeping pace with the femur in the vertical growth of the limb, and had thus produced slow and continuous hyperextension. It was decided therefore to separate the adherent portion of muscle from the bone, and thus to overcome the hyperextension, and to reestablish the normal relations of the articular surfaces of the knee. An operation, which consisted in subcutaneous detachment of the quadriceps from the femur, and in division of the tense cord formed by the lower part of the muscle, was followed after a time by satisfactory results. The limb, it is stated, was restored to the normal position, and there was a fair though not complete range of the movements of flexion and extension at the knee. —*British Medical Journal*, Jan. 29, 1898.

#### THE RADICAL TREATMENT OF HYDROCELE.

BLOCK (*Revue de Chirurgie*, Feb. 2, 1898) describes a new operation for the radical cure of hydrocele of the tunica vaginalis. The old method of injection of iodine, he points out, causes a very painful inflammatory reaction, and, in common with the more recent treatment by incision and drainage, necessitates prolonged rest in bed, and does not insure freedom from relapse. The author makes a free incision into the sac, applies a three-per-cent. solution of carbolic acid to the surface of the exposed testicle and the whole of the inner surface of the tunica vaginalis, and stuffs the cavity with strips of iodoform gauze. After removal of the gauze, on the third or fourth day, the wound in the skin is closed by catgut sutures. Of eighteen cases treated by this method, the patients having been seen after intervals between eight months and five years from the date of operation, in one only was a relapse noted. This was a case of very large hydrocele in a man aged sixty-four years. —*British Medical Journal*, March 12, 1898.

#### OPERATIVE TREATMENT OF CONGENITAL UMBILICAL HERNIA IN THE NEW-BORN.

K. HEDMAN (*Finska Läkare-sällskapets Handlingar*, December, 1897) has operated upon a case of congenital umbilical hernia in a new-born infant. The hernia was of

the size of the little finger and contained liver and small intestine, which could be seen through the translucent sac wall. Attempts at taxis proved that the abdominal cavity could contain the herniated organs. The little patient, who weighed 3600 grammes, was put under chloroform and a needle with silk ligature was passed through the skin elevation, and the silk was gradually tightened as the contents were returned to the abdomen. The umbilical vessels in the sac wall were separately ligatured. The hernial pouch was then cut off, and the wound closed with silk sutures. The operation, which lasted an hour and a half, was successful, but was followed by the development of a bilateral inguinal hernia. —*British Medical Journal*, Jan. 29, 1898.

### Reviews.

THE DISEASES OF THE STOMACH. By William W. Van Valzah, A.M., M.D., and J. Douglas Nisbet, A.M., M.D. Illustrated. Philadelphia: W. B. Saunders, 1898.

This book is unusual in that it does not contain any distinct preface. It is divided into six sections, the first of which consists of an Introduction and Classification; the second with Diagnosis and Diagnostic Methods; and the third with Medication. Following this we find sections on Dynamic Affections of the Stomach, and Diseases of the Stomach Wall. The sixth section has the rather curious title of The Vicious Circles of the Stomach. This latter section is devoted to a consideration of the diseases of the stomach as they affect the other organs of digestion and assimilation, and with the diseases of these organs as they affect the stomach itself. This portion of the book might be the most interesting and original part of the volume, as it is so far as we know a part of gastrology, if we may use such a word, which has not as yet received the attention which it deserves. Unfortunately this part is not as exhaustive as we think its importance demands. On the other hand, the rest of the book gives evidence of the fact that its authors have had a large experience in the treatment of gastric disorders, and while it is not as exhaustive, in the sense of the consideration of general literature, as is the volume by Hemmeter which we have recently reviewed, or the volume of Ewald translated by Manges, it is, on the other hand, a mirror of the authors' personal experiences.

The exact position which this book will

take in American Medicine we cannot definitely determine. It is written in rather a conversational style, as if it might have been dictated to a stenographer, and we think might have been condensed with advantage. The most attractive thing about the volume to us is the knowledge that its authors are physicians of wide experience in the study of dietetics and the treatment of digestive disorders.

**REPORT ON BUBONIC PLAGUE.** Being a Report Based upon Observations on 939 Cases of Bubonic Plague Treated at the Municipal Hospital for Infectious Diseases at Arthur Road, Bombay, from September 24, 1896, to February 23, 1897. By Khan Bahadur N. H. Choksy. Reprinted by Authority.

Bombay: Printed at the "Times of India" Steam Press, 1897.

This is a monographic report covering fifty-seven large imperial pages and followed by a number of temperature charts illustrating the progress of the disease under discussion. It begins with a description of the hospital in which the cases were studied, and then goes on to a consideration of the manifestations of bubonic plague in connection with the various organs of the body. In doing this it deals with the diagnosis, the prognosis, and the treatment, and finally with the causes of death and the post-mortem appearances of the various organs. To those who are interested in this disease of the tropics this report will prove interesting and valuable reading. It is interesting to note on the thirteenth page of the report a table giving the comparative mortality of the disease in various occupations. The table shows that classes which are generally well fed have a far better chance of getting over the infection than those not similarly situated. Thus, for example, among domestic servants the mortality was 65.47 against 89.47 among the very poorest classes.

In regard to the situation of the bubonic lesion, out of 856 cases there were 275 femoral buboes, 200 femoro-inguiinal buboes, 140 axillary buboes, and 106 inguinal buboes, the remaining cases being distributed well over the body. Curiously enough, double inguinal bubo and double cervical bubo were only met with in one case. The report does great credit to its author.

**DIE ZUCKERKRANKHEIT UND IHRE BEHANDLUNG.** Von Professor Dr. Carl von Noorden. Berlin: August Hirschwald, 1898.

Professor Von Noorden is perhaps the leading authority to-day concerning the disease diabetes mellitus. Certainly he is to be considered the leader if we confine our remarks to the medical profession upon the European

Continent, and his researches in connection with the pathology and etiology of this disease have made his name familiar to physicians everywhere. The object of the present volume is well described in its title, Diabetes Mellitus and its Treatment. In the earlier pages he discusses the physiology and general pathology of sugar transformations in the body, then goes on to a consideration of the theories concerning diabetes mellitus, its etiology, pathology, and complications; and it is in the part devoted to the complications which we have found the greatest interest. Other chapters then follow upon the Diagnosis and Prognosis, and finally in the seventh chapter there is an exhaustive *résumé* of the methods of treatment, both prophylactic, dietetic, hygienic, and medicinal. The volume is an exceedingly valuable one, although the article upon Diabetes contributed by Professor Von Noorden to the Twentieth Century Practice of Medicine contains most of the information which this monograph presents to us.

**DAY-DREAMS OF A DOCTOR.** By C. Barlow, M.D. Buffalo, New York: The Peter Paul Book Co., 1898.

The author of this book has provided his fellow practitioners with a semi-biographical sketch of his own life and that of other practitioners. Nine rather crude illustrations accompany the text, and some of them are so poor that the book would have been better without them. The book is written, the author tells us, because the medical profession as a useful and even indispensable factor to mankind has never been fully appreciated, and he endeavors to describe the peculiar life and work of the physician and the difficulties with which he has to contend, hoping that non-medical readers will peruse the pages quite as much as members of the profession.

**DISEASES OF WOMEN.** By George Ernest Herman, M.B. Lond., F.R.C.P. Illustrated. New York: William Wood & Company, 1898.

This work the author states he has written because it seemed to him that a book was wanted which should guide the student and practitioner to the diagnosis and right treatment of the diseases of women. The reviewer had thought that Skene, Kelly, Garrigues, Penrose, Madden, Dorland and a few other gynecologists partially supplied this need, but apparently this is a mistake.

Herman asserts that he has sought to state principles, and in applying those principles to recommend that which, having tried, he

knows to be good. In this relation it is interesting to note that the most reliable sign by which a diagnosis can be made between peritonitis and abdominal shock is the expression of the face. We are told "if the expression of the face is cheerful, hopeful, contented, and placid, the patient will do well, notwithstanding some apparently unfavorable symptoms."

The author has a happy rhetorical faculty which enables him to employ similes in a way that is quite his own; thus we read, "If the patient be losing copiously each month, it is like carrying coals to Newcastle to take blood from the womb."

The reviewer is pleasantly impressed with the individuality of the writer when in glancing over the volume he finds in large black print such titles as, "Importance of Reproductive Function to Women," "Value of Matthew Duncan's Teaching," "Subject of Next Five Chapters," and "Why Wrong Views Have Prevailed."

Although there are certain features in this work which seem somewhat unusual to the American mind, it may be said that Herman has compiled a work the woof and warp whereof is common sense, backed by a large experience.

AN AMERICAN TEXT-BOOK OF GENITO-URINARY DISEASES, SYPHILIS, AND DISEASES OF THE SKIN. Edited by L. Bolton Bangs, M.D., and W. A. Hardaway, A.M., M.D. Illustrated.

Philadelphia: W. B. Saunders, 1898.

This long-heralded book, covering as it does genito-urinary diseases, syphilis, and diseases of the skin, excellently and sufficiently illustrated and edited by men of acknowledged eminence, is quite certain of a cordial reception at the hands of the profession.

Of the 1200 odd pages which comprise the volume, nearly two-thirds are devoted to genito-urinary surgery. It will be noted that the work is cooperative and that the collaboration of perhaps the leading authorities in special branches has been secured. The first chapter, by Thorndike, is devoted to a consideration of the Urine in Surgical Diseases of the Urinary Tract. This rather extensive subject has been admirably condensed and put into a serviceable form.

Farquhar Curtis and Lydston contribute extremely valuable sections on Diseases of the Penis and Diseases of the Male Urethra respectively.

Fuller has written upon Diseases of the Testicle and its Coverings, the Cord, and the

Seminal Vesicle, and in his characteristically forceful manner.

White and Wood have lucidly summarized Diseases of the Prostate, devoting especial attention, as might be expected, to castration as the treatment for hypertrophy.

Watson's article on Stone, as might be expected, is entirely satisfactory.

Fenger and Stanton have written a section on Diseases of the Ureter which would be sufficiently comprehensive for an encyclopedic work.

Pederson should be commended for the excellent manner in which he has handled the exceedingly difficult subject of Functional Disorders.

In the section devoted to Dermatology will be found chapters by Hardaway, Van Harlingen, Hartzell, Klotz, Winfield, Robinson, Cantrell, and other well known dermatologists.

Dr. Bangs is to be congratulated upon an extremely skilful piece of editorial work in molding the contributions of so many authors into a very symmetrical and evenly balanced volume. There is little doubt as to its success.

### LONDON LETTER.

BY RAYMOND CRAWFORD, M.A. OXON., M.D., M.R.C.P. LOND.

Dr. Kingscote opened an interesting discussion at the Medical Society of London on the "Vagus Origin of Asthma and its Treatment." It would have been well if he had started with some exclusive definition of the term "asthma," which was somewhat loosely employed to cover both cardiac dyspnea and true spasmodic asthma. We would further question the substantial accuracy of his major premise that asthma is a symptom of vagus irritation, though it is true that asthma has been experimentally produced by stimulating the proximal end of the divided vagus. Far more probably it is due to some rapidly occurring congestion of the vessels leading to turgescence of the bronchial mucosa. Such a pathology would explain the frequent relationship of hay-fever and hay-asthma, the former being associated with congestion of the nasal, the latter with congestion of the bronchial, mucous membrane. Dr. Kingscote thinks that many cases of asthma are due to pressure of a dilated heart on the vagi as

they lie behind it against the bony spine, and has found relief for many cases by measures directed to reducing the size of the heart. He employed a modified Schott treatment combined with inhalation of oxygen in cases where such cardiac dilatation could be shown to exist. It is true that not long since Ortnier maintained, and with some show of reason, that in mitral stenosis the enlarged left auricle sometimes compressed the recurrent laryngeal, but there is really no evidence to show that the trunk of the vagus can be compressed by a generally enlarged heart. Maguire dissented from the theory on the ground that the thoracic viscera work under a negative pressure, which would tend *pro tanto* to diminish any pressure upon the vagus. Dyspnea of a more or less paroxysmal character is of course a familiar feature of great dilatation of the heart, but the dyspnea is not asthma and is not due to the pressure of the heart on the vagus. Iodide of potassium is commonly regarded as a valuable antispasmodic in the treatment of asthma, but far more probably its efficacy is due to liquefying the secretion, so that it is more readily expelled, and to its undoubted influence in allaying inflammations.

A few months ago we mentioned the successful treatment of several cases of inoperable sarcoma by Mansell Moullin with Coley's fluid, and now another case has been brought forward by Battle of a rather different character. This proved on examination of an excised portion to be a fibro-sarcoma with giant cells. The few notes of the case are of interest, as so many medical men are skeptical of the efficacy of this treatment. Four months before the man came under observation he noticed a lump under his right arm, which was soon followed by the appearance of other swellings. Shortly before admission to hospital a tumor formed over the right clavicle, and another over the right side of the sternum, while there were numerous enlarged glands in the axilla. The man had had syphilis six years previously, so was treated with iodide of potassium in large and increasing doses, but without improvement. At this stage examination of the growth determined its malignant character, and for two months half-minim doses of Coley's fluid were administered every other day, the iodide being maintained during the greater part of this period. The man had benefited materially in general health, and at the present time there were only two small swellings remaining. An unusual feature of the case was the absence of any reaction, the

temperature having been normal throughout. This case is an interesting supplement to the series already published both by Coley and Mansell Moullin. With all the accumulated evidence no reasonable being can doubt that certain sarcomata do completely disappear under this treatment, and a faithful record of all such cases would serve in time to establish the conditions under which we may look for success. At present we are completely in the dark in attempting to explain the undoubted disappearance of malignant tumors under various agencies. At the present moment I have under my care a patient whose abdomen was opened several years ago by a leading London surgeon. The upper part of the abdomen was found filled with a diffusely growing tumor, which presented all the features of malignancy; accordingly the incision was closed, and the patient sent back to the ward to die. From this time the tumor steadily diminished in size, and in the course of twelve months ceased to be palpable. He has now come under my care with jaundice, which seems to be due to some persistent obstruction, but there is no trace of a tumor, and one can only guess at the mechanism of the obstruction.

Mr. G. R. Turner records a case of neuralgia cured by injection of osmic acid into the nerve. The patient, a woman aged thirty-three, had suffered from severe neuralgia for two years, and had derived no relief from various forms of treatment. The pain was at first limited to the infraorbital nerve, but had subsequently spread to the other branches of the fifth nerve, and was accompanied by a discharge from the right nostril. A one-per-cent. aqueous solution of osmic acid was injected by a hypodermic syringe into the infraorbital nerve within the infraorbital canal. The injection was followed by pain and tenderness for some ten days, but as soon as this passed away the patient was quite free from pain. Mr. Turner suggested that the acid destroyed the nerve fibers, but it is questionable whether simple acupuncture might not have effected a similar result.

Surgeon-Captain Johnston communicates to the *British Medical Journal* of April 16 his experience in the treatment of tropical dysentery with magnesium sulphate. He had at first used Glauber's salt, but soon rejected this in favor of magnesium sulphate. His line of treatment is as follows: He first of all places the patient on an exclusively milk diet, and then gives two drachms of sulphate of magnesium every four hours, combined with aromatic sul-

phuric acid to prevent griping; the mixture is stopped as soon as the character of the stools indicates a free flow of bile, and a quarter to a half of a pure gallnut is given instead, well triturated with water, every four hours. Two or three days of this treatment usually suffices to cure the dysentery, permitting a return to soft diet. He suggests that the flow of bile performs an important function in intestinal antiseptis, and that the purgative action of the salt prevents putrefaction by flushing out the bowel. Hale White not long since obtained excellent results in the treatment of dysentery simply by rest in bed with large doses of bismuth.

In *The Lancet* of April 23 Lynn Thomas, of Cardiff, describes a simple method for controlling hemorrhage during disarticulation at the hip, which he had employed successfully. The method effects temporary compression of the femoral artery and vein immediately below Poupert's ligament, where the artery is superficial and easily felt, and well above the origin of the profunda femoris. He first accurately locates the femoral pulse, and then makes two stab punctures in the skin, one about an inch outside the pulse and another about two inches inside it. A two-eyed aneurism needle is then thrust from one stab to the other, keeping well behind the vessels, and two long, thick, silk ligatures are carried across on withdrawing the needle. A pad of Gamgee tissue is then rolled up and placed between the stabs, and the two silks are tied separately over the roll so as to compress the vessels. It is best simply to tie the first stage of the surgeon's knot, and then to clamp it with forceps, so that it can be readily retied if necessary when letting go after ligature of the visible blood-vessels on the face of the stump. Another method of controlling the vessels in an emergency is by means of a pair of Doyen's broad ligament forceps; only one puncture is made on the outer side of the femoral pulse, and one blade is thrust through this and behind the femoral vessels, when the forceps are clamped. The former method is one that deserves attention, as the necessary instruments form part of every surgeon's paraphernalia; but the latter is less likely to be serviceable, as it necessitates the use of an instrument which would not be at hand in the ordinary course of operation.

A few months ago we drew your attention to some observations of Dr. Clifford Beale on the administration of large doses of creosote in pulmonary phthisis. Drs. Squire and

Stanford Read have recently reported the results of a similar experience with guaiacol. Of their patients six took sixty minims, two took fifty minims, four took forty minims, six took thirty minims, ten took twenty minims, six took fifteen minims, and six took ten minims, three times a day after food. The drug was administered either in five-minim capsules or in emulsion with glycerin and tincture of orange, or in both ways simultaneously. Some patients preferred the one method, some the other, but the drug seemed to be much better tolerated when taken with a good draught of milk, which apparently diminishes the irritation of the mucous membrane that the drug is liable to excite. The initial dose was usually five minims, and five minims was added every other day to each dose until sixty minims was reached. In only one instance was there any evidence of serious digestive disturbances, and in this case the drug was again administered after a short respite and with success. Twenty-six of the cases had pulmonary cavities, and in all of these there was a marked diminution in the amount of expectoration, and in the fetor. Another effect of this liberal dosage was a steady lowering of the evening temperature. Most of the cases steadily increased in weight under the treatment. Cough did not appear to be relieved, but night sweating was markedly diminished, not infrequently to complete disappearance. At present no observations have been made on the number of bacilli in the sputum, but we are promised information on this point at a later date.

---

#### PARIS LETTER.

---

By A. R. TURNER, M.D. (PARIS).

---

Among the theses presented at the Faculty of Medicine during the past year, one, by Dr. Mercier, on enteroclysis in new-born infants, is of practical value. The author of this work has followed the counsels of his instructor, Dr. Bonnaire, and he begins by giving us some important anatomical facts on the subject. The length of the small intestine in the new-born infant is, it seems, 260 centimeters, and that of the large intestine 55 centimeters. The latter holds from 100 to 200 cubic centimeters. One fact to be remembered is that the ileocæcal valve is insufficient, as Krauss has demonstrated. The following mode of procedure should be adopted: The apparatus consists of a glass

receptacle, which may be raised from 60 to 70 centimeters above the infant. It is connected by means of a rubber tube with a Nelaton's soft-rubber catheter, from 15 to 20 Charrière in number. The catheter is to be gently introduced into the rectum until some slight resistance is felt. It will then have penetrated about 15 centimeters. The child is placed on its right side, lying across the knees of the physician, and the catheter should be kept in place by the physician, who should prevent the liquid escaping from the rectum until it has been totally injected. About one-half a liter may be used, of either boiled water and boracic acid, or with sodium chloride, or of the following preparation:

Boiled water, 1000 Cc.;  
Borax, 10 Gm.;  
B-naphthol, 1 Gm.

The injection should be tepid, and once the 500 cubic centimeters has completely passed into the intestine, the liquid may be allowed to escape, either through the catheter or directly. This operation should be carried out twice daily until all morbid symptoms have vanished. It is to be highly recommended in the various intestinal disturbances in the new-born infant, for fetid stools and stools green in color, gastro-intestinal infection, and tympanites. It is neither a difficult nor dangerous method.

An article by Dr. Plesoianu, of Bucharest, published in the *Presse Médicale*, gives an account of the results obtained by the use of atropine in cases of dyspepsia attended by excess of hydrochloric acid. In it he notes what has been done in Russia by Drs. Nitchaiew and Panow with this drug. It has likewise been used in France by Bouveret, Mathieu, and Hayem. It should be remembered that this form of dyspepsia is accompanied not only by hypersecretion, but by pain, and as a necessary sequence by a certain degree of spasm, which may occur at the pylorus causing retention of food in the stomach. Atropine is consequently most useful in such cases, as it diminishes the secretions, decreases pain, and reduces the spasm. It acts much more energetically if applied locally, namely, by the mouth.

How shall it be administered? Bouveret and Devic gave it hypodermically, but did not obtain favorable results. Dr. Plesoianu recommends the following method:

Atropine sulphate, 1 centigramme;  
Distilled water, 10 Cc.

Ten drops of this solution are to be given

daily, divided into three doses. The dose may be increased in two to three days to twenty drops daily, provided no untoward symptoms develop, and then drop by drop the dose may be carried to fifty drops, and then reduced in the same way to twenty drops. Thus from one to two milligrammes are given daily.

Dr. Pouchet, professor of pharmacology at the Faculty of Medicine, recommends the following prescription:

Atropine, 1 centigramme;  
Glycerin (28-per-cent.), 3.5 Cc.;  
Distilled water, 1.3 Cc.;  
Alcohol (95-per-cent.), sufficient to make up 10 Cc.

Fifty drops of the above are equivalent to one milligramme of atropine.

The important factors in the method of treatment are exact doses and gradual increase. Attention should be given to the danger-signals of atropine poisoning, such as dilatation of the pupil, dryness of the throat, and flushing of the cheeks.

The Ninth International Congress of Hygiene has just been held at Madrid. It would have taken place last year, but for the disturbances in the Spanish colonies. As this has been the first occasion on which an international congress has been held in Madrid, the Government endeavored to make it a success. About 1600 medical members were present, and all European nations, with the exception of Russia and Denmark, were represented. Some official representatives were sent by the Government of the United States. One hundred and eleven delegates came from France.

The Congress was opened on the 10th of April in the great lecture room of the Palace of Museums and Libraries. Dr. Juan Calleja, Dean of the Madrid Faculty, made the opening speech, and in it he referred to the painful situation in which Spain found herself, and to the soldiers then engaged in warfare. He described the benefits to be derived from hygiene, and defended this science against the accusation of limiting the liberty of individuals. After a second speech by Dr. Amalio Gimeno, the Queen Regent and her son, Alfonso XIII, inaugurated the Exposition of Hygiene, and the principal delegates were presented to Her Majesty.

During the various sessions, bacteriology and the study of toxins and poisons seem to have occupied the greater part of the members' attention. Spronck, of Utrecht, communicated this fact, that by heating diphtheria

serum to 50° C. the various noxious elements were destroyed without injuring the properties of the serum.

Dr. Calmette, director of the Pasteur Institute at Lille, read an interesting report on immunization against the venom of serpents.

One of the most important communications was that of Dr. Chantemesse, of Paris, on the serotherapy of enteric fever. Dr. Chantemesse has prepared in the usual manner a vaccinating serum for animals, having, however, no action on the disease once declared. The toxin of typhoid fever is elusive, and Dr. Chantemesse has not succeeded in discovering it in the ordinary media used for the cultivation of microbes. By using a maceration of spleen and bone-marrow with a small quantity of defibrinated human blood an active toxin was obtained. More recently he has used spleen digested by pepsin obtained from pigs. The horse has been used at the Pasteur Institute in Paris as a means of producing an antityphoid serum. Two to three years were required to do so, as the toxin remains a long time in the blood of the horse. If this serum be used on guinea-pigs and rabbits, they resist subsequent injections of the toxin of enteric fever; and if the bacilli be injected under the skin, some hours later no free bacteria are found, but all are contained within the white blood-corpuscles, and in polynuclear leucocytes they are transformed into small spherical bodies.

In a last series of experiments Dr. Chantemesse was enabled to establish the antitoxic properties of his serum. He noted that the doses must be increased in proportion to the time since inoculation. Tried on patients suffering from enteric fever, Dr. Chantemesse finds that the serum lowers the temperature, ameliorates the nervous symptoms, and hastens recovery.

---

#### BERLIN LETTER.

BY JAMES J. WALSH, PH.D., M.D.

The therapeutic features of the recent German Congress for Internal Medicine at Wiesbaden will, I am sure, be interesting to American doctors. Though most of the papers read were eminently practical, and most of them contained more than a passing reference to therapy, while two of the subjects out of three selected for discussion were the treatment of diabetes and of intestinal autointoxication, yet very little was said of drugs.

In his paper on the clinical teaching of medicine, Professor von Ziemssen, of Munich, insisted that much more attention than formerly would have to be given to the physical therapeutic methods, and that every clinic would have to have in connection with it departments in which electrotherapy, balneotherapy, dietotherapy, massage and gymnastic and movement therapy would be practically taught.

Professors Quincke (Kiel) and Jürgenson (Tübingen) insisted that the present teaching of therapeutics was on the whole too exclusively pharmacological, and that time spent in learning the physiological effects and uses and methods of prescribing a number of drugs that would be rarely if ever used might be profitably devoted to physical therapeutic methods. During the discussion it was pointed out that even the principles of climatology might be practically taught in a clinic, by calling the attention of students to the ailments that characterize certain seasons of the year, and the symptoms that develop in patients in consequence of meteorological and barometric changes.

In the treatment of diabetes Professor Leo outlined the method which is now generally followed by clinicians in Europe, especially by all such as believe with Naunyn, of Strasburg, that even lighter cases may gradually pass into the severer forms. Not all the carbohydrates are withdrawn, but so much allowed as keeps the urine sugars free or practically so—*i.e.*, under one-half. Then three or four times a year, for intervals of two or three weeks at a time, absolutely all carbohydrates are interdicted. It is considered that the perfect rest of the sugar metabolic faculty for a time enables it to recuperate better than by allowing only slight demands to be made on it, but persistently. In the matter of prophylaxis Professor Leo's observations as to the production of mellituria in dogs, when fermenting solutions of sugar were fed them, seem to be considered of importance here in Germany, where diabetes is undoubtedly on the increase, and where according to many this increase bears a constant relation to the increasing amount of fermented liquors that are used.

As to specific treatment, Professor Leo has been employing with certain good results in animals, and a modicum of success in human patients, compressed dried yeast; the idea seemingly being to lead to the conversion of ordinary carbohydrates into a chemical

modification which the system can make use of, though it cannot use sugar straight. It may be mentioned here in passing that in discussing the treatment of intestinal auto-intoxication Professor Quincke, of Kiel, reported that he had had good results with yeast administered in small quantities by the mouth. He considered that the presence of the yeast cells led to chemical changes in the intestinal contents, which caused the splitting up of dangerous toxins into innocuous or unabsorbable compounds. These two attempts to use biological processes within the body for therapeutic purposes seem worthy of note as pioneer work.

Professor von Jaksch views the treatment of diabetes in a new light. He considers that in a few years we will think it as foolish to devote all our attention in diabetes to the lessening of the sugar in the urine as we do now to give antipyretics in infectious diseases to keep fever down, though every one was doing it a few years ago. Fever and glycosuria are both but symptoms. The important thing is the general condition of the patient; that suffers because the patient is not able to make use of the carbohydrates in the ordinary forms. Of levulose, however, he can make much more use than of dextrose. It is possible that there is a carbohydrate for which even diabetics retain the metabolic faculty. A series of experiments with various of the sugar series has not given him the hoped for result, though arabinose-methyl pentose proves even more available for diabetics than levulose, so that there is encouragement to proceed with this line of investigation.

It seems to be agreed that saccharin is not the harmless, indifferent, sweetening material it has been considered to be, but a rather powerful drug. In fermentative enteritis Boas has gotten good results from it as an antiferment. Von Jaksch thinks this antiferment action interferes with digestion and is the cause of the digestive troubles that so often occur in diabetes, when saccharin is in any way freely used.

Professor von Leube (Würzburg), following the suggestion of Professor Minkowski of Strasburg, is trying pancreatic extract, though he is not yet able to report definitely as to results. Minkowski found that the artificial diabetes of dogs, produced by removal of the pancreas, could be relieved by the administration of pancreas extract.

Subcutaneous injections of sugar have been tried by several clinics. As much as 100

grammes of sugar may be given at an injection without producing glycosuria. The results are not very encouraging, however, and the points of injection become infiltrated and easily suppurate, besides causing a great deal of pain. The discussion brought out the fact that subcutaneous injections of olive oil as nutritive material in cancer or stricture of the esophagus or pylorus is now in use in a number of clinics and is giving very satisfactory results.

For intestinal autointoxication very little confidence is placed in so-called intestinal disinfectants. If the absorption of toxins is taking place from the stomach, as in dilatation of the stomach, then that organ is to be washed out; if from the intestines, a prompt purgative is to be employed; while in chronic cases flushing of the colon is also considered desirable. Dr. Boas called attention to the fact that in many of these cases of acute intestinal autointoxication there is great reduction in the quantity of urine passed, sometimes almost complete suppression of urine supervening. In such cases calomel does good, not so much because of any intestinal disinfectant action, but because of the diuresis it produces. In every case he thought immediate steps should be taken to secure prompt diuretic action, for here lay the greatest danger.

For the treatment of the long-standing cases of chlorosis, that so often prove obstinate to all treatment and relapse so readily, even after ordinary therapeutic measures seem to have accomplished some good, hot baths were suggested as a remedy that seems to excite the blood-making organs better than anything else. They are of special service in the cases complicated by an intense feeling of muscular tiredness—a feeling that is really due to muscular exhaustion, not brought on by exertion, but by lowered nutrition from the impoverished blood. How restful in the ordinary tired states are warm baths is well and popularly known. Often in these long-standing cases of chlorosis there is almost a painful sense of fatigue in the muscles, and this is promptly relieved.

Hot baths increase the excretion of the carbon compounds in the urine. This is taken as an indication that sluggish metabolic processes, especially in the muscular system, have been excited into greater activity. An increase in the alkalescence of the blood is also demonstrable, and it is this that is thought to have a tonic effect upon the blood-making organs and to increase the

nutriment carrying power of the blood by setting it in a state of more stable equilibrium.

The hot baths are given at a temperature as high as the patients can bear them—at least 32° Reaumur (104° Fahrenheit)—and the patients are made to sweat plentifully during the bath. A towel wrung out in cold water may be placed on the head to avoid unpleasant cerebral sensations from circulatory disturbance within the cranium, but this is seldom necessary. A bath is given three times a week for three or four weeks, when the improvement will be such as to make further exact hydrotherapy unnecessary. Each bath lasts one-half to three-quarters of an hour and is followed by a gentle cold douche of 75° to 80° Fahrenheit, in order to avoid after sweating, which would be exhausting.

The discussion brought out the fact that a number of clinicians are now using venesection for very obstinate cases of chlorosis, and with excellent results. It is thought to have two effects: first, to produce an immediate intense reaction upon the blood-making organs, and second, dilute the toxins in the circulation, which are at once the cause and effect of the sluggish cellular metabolism and of absorption, as so many believe, of unsuitably prepared albumoses from the intestinal tract in the constipation that is so usually an accompaniment of the disease.

A little startling in the line of therapeutics is the suggestion of Dr. Jacob, of Leyden's clinic, in Berlin. He proposes in disease of the central nervous system to inject drugs directly into the subdural space. The absolute security with which a lumbar puncture may now be done indicated that some further step in this line would come. The Quincke puncture, though expected to be of great use in therapeutics, has only proved of service in meningitis serosa, and simple meningitis not due to bacteria, though there are some wonderful cures reported in extremely threatening cases. Jacob has been able to inject 150 cubic centimeters of various solutions of drugs into the spinal canal of animals without causing symptoms. In two cases in human beings a solution of iodide of potassium has been so injected without any untoward results, though the cases were too far gone to hope for anything but passing amelioration of symptoms.

Another bit of therapeutics of the future perhaps, though as yet it has not gotten beyond the test tubes, is also reported from

Leyden's clinic. Blumenthal has found in the liver and pancreas glycolytic substances, compounds that so act on sugar as to put it into a state of chemically unstable equilibrium, in which form it is thought it will be readily absorbed even by diabetics. But this needs confirmation in clinical experience.

#### *APOCYNUM CANNABINUM.*

NEW ORLEANS, April 27, 1898.

To the Editor of the THERAPEUTIC GAZETTE.

SIR: I take the liberty of sending to you, in your capacity as Editor of the THERAPEUTIC GAZETTE, a monograph of mine entitled "Treatment of Dropsy." This article was written nearly twenty years ago to induce the profession to abandon the routine tapping, purging, etc., in such cases. The one remedy I recommended was *Apocynum Cannabinum*. On page 253 (April 15, 1898) of the THERAPEUTIC GAZETTE you are pleased to place this remedy under the caption of "Therapeutic Progress of 1897," the remedy having been favorably mentioned at the meeting in Montreal last year. Knowing your fairness in all literary matters, I thought you would be glad to see that a citizen of the United States had been the first to call attention seriously to this very valuable remedy. My cases reported are of record in the Charity Hospital. I used the apocynum before I knew its botanical name, and not until I had decided to make public my observations did I find out the exact name of my weed, which grows abundantly in certain parts of the South. By reading carefully what I wrote nearly twenty years ago, you will find out that nothing new has been discovered in reference to this remedy. I have persistently used it ever since, and never in *one* instance have I had to resort to tapping.

I hope you will, through the columns of the GAZETTE, give credit to whom credit is due. I am writing to Dr. Sajous on the same subject. He, on page 33, in his January, 1898, journal, quotes from Dr. A. A. Woodhull's paper (*British Medical Journal*, Dec. 11, 1897) some things about the apocynum as if Dr. Woodhull had discovered it. Thanking you in advance, I remain,

Yours truly,

T. S. DABNEY, M.D.

[In publishing the abstract referred to above there was no intention except to call attention to apocynum. We are very glad to give Dr. Dabney the credit he deserves.—Ed.]

### ERGOT ASEPTIC.\*

BY E. M. HOUGHTON, PH.C., M.D.,  
Lecturer on Experimental Pharmacology, Detroit College of Medicine; Member of the American Medical Association, etc.

Many attempts have been made to isolate the active constituents of ergot, or to produce a satisfactory preparation of the drug for hypodermic administration. Owing to the fact that pharmacologists thus far have not been able to agree upon what should be con-

sidered the active constituents of ergot, and the great difficulty of isolating the chemical constituents already studied, it seemed to me best to endeavor to obtain a preparation which would represent as nearly as possible the activity of prime samples of ergot, rather than to attempt to obtain any of the constituents of the drug in pure form.

It is not necessary to mention the importance of having a reliable preparation of ergot for hypodermic administration always on hand when prompt action of the drug is desired. Especially desirable is this in obstetric practise, since it so frequently happens that at the critical moment the patient is vomiting, or the stomach is otherwise not

\*Read before the Michigan State Medical Society, Detroit, May 6, 1898.

in condition to absorb the drug when administered by the mouth.

It is a well known fact that much of the crude ergot, and its preparations, on the market vary very greatly in strength, or may be entirely inert; consequently it seemed advisable to adopt some method of physiological assay. Having this in view, various methods of determining from physiological experiments the real activity possessed by ergot were investigated. I finally decided to adopt the reaction manifested in roosters when fed with this drug. From times prehistoric it has been observed that in fowls, swine, and other animals, as well as man, fed with ergotized rye, or with bread prepared from the flour of such grain, for a considerable length of time, the poisonous action of the fungus is frequently manifested by gangrene and sloughing of the peripheral parts, as the comb of fowls, ears of hogs, and ears, nose, fingers and toes of man. Two particular types of ergot poisoning have been observed in man, viz., *ergotismus gangrenosus* and *ergotismus spasmodicus*. Kobert, and his pupil Grünfeld, were the first to employ the method of feeding ergot to roosters in order to determine the activity of the crude drug, or of the products isolated from it. However, these investigators employed the reaction only for experimental purposes. It seemed to me, after careful investigation, that it would be advisable, and of vastly more importance to medical practitioners, to employ this reaction not only as a check on experimental work, but as a means for determining the active properties of the crude ergot before its manufacture into the various pharmaceutical preparations, and to test the completed preparations by the same means. With this end in view I have examined during the past three years several hundred samples of the crude drug as it appeared upon the American market, and finished preparations taken from the druggists' shelves. Many of the samples were almost inert, while the remainder varied greatly in activity. Indeed, not long since I had occasion to reject several samples of the drug which were forwarded to me for examination, the aggregate quantity represented by them amounting to over 20,000 pounds. This method of testing was employed also by Jacobi last year in an elaborate experimental research. My experience leads me to conclude that not more than from fifty to seventy-five per cent. of the drug, or its preparations, offered for sale is suitable for medicinal use.

In taking up the study of ergot aseptically I shall present the views of some of the leading pharmacologists who have made extended researches on ergot. It has been shown that the fungus contains acid salts of potassium, sodium, etc., and various organic constituents, as coloring matter, fats, methylamine, etc. These several constituents are of little importance if contained in preparations designed for internal administration, since none of them are physiologically active, but they may be a source of irritation when injected subcutaneously. Pharmacologists in general agree that ergot contains at least three active constituents, viz., ergotinic acid, sphacelinic acid, and cornutin. Ergotinic acid (the impure form of which is known as sclerotinic or sclerotic acid, and combined with mannin is known as scleromuscine) is a glucosidal body, readily soluble in water but almost insoluble in alcohol; it decomposes easily under bacterial or chemical influences. Consequently, when taken internally in the various preparations of the drug it is quickly split up by the processes of digestion, or by bacteria contained in the alimentary canal. Dragendorff and Podwyssotzki were the first to call attention to this constituent, and claimed, because they found that it stopped the laid-bare frog's heart in diastole, that it was the active constituent to be depended upon for the production of ergot effects. The later work of Kobert, his pupil Grünfeld, and others, has shown that it has no influence on the uterus, not even when gravid. Since it is decomposed and not absorbed from the alimentary canal, except possibly in the minutest quantities, it is not objectionable when contained in preparations for oral administration, but is to be especially guarded against in fluids designed for hypodermic use, since when administered in this manner it is slowly absorbed into the system—in fact (according to Kobert), it acts as a long-irritating foreign body, frequently resulting in abscess. As much as three per cent. of sclerotic acid may be obtained from some of the preparations of ergot on the market. I will add several volumes of strong alcohol to this fluid extract of ergot, and you can better appreciate this fact, since the voluminous precipitate thrown down consists almost entirely of this constituent. When subcutaneously injected in a very dilute condition, sufficient quantities may be absorbed to produce the general symptoms noted when the drug is introduced directly into the intravenous system—that is, the irritability of

the central nervous system is lessened. The action of ergotinic acid on the spinal cord is manifested by paresis, weakness of the limbs, etc., large doses producing complete motor and finally sensory paralysis. Blood-pressure is also lowered, from the action of the acid on the vasomotor centers, while its sedative action on the brain is manifested by stupor.

I have repeatedly confirmed these statements by subcutaneous and internal administration of the ergotinic acid to roosters, and to pregnant animals in various stages of gestation.

Ergot affords one of the many instances where, possibly by a wise provision of Nature, a crude drug contains active constituents having antagonistic actions. Sphacelinic acid, which is also known by the names of sphacelotoxin and sphacmotoxin, is a resinous substance almost entirely insoluble in water, but readily soluble in alcohol. It has not been obtained in a pure condition, as it is very easily decomposed by chemical manipulations. It is held that this substance is responsible for the ergotismus gangrenosus. This constituent was first obtained by Kobert, and later extensively studied by Grünfeld, who concluded that while it had marked pharmacologic properties it could not be used therapeutically. This opinion, however, was disputed last year by Jacobi, who holds that the active constituent of ergot is the nitrogen-free resin, sphacelotoxin, which occurs in the drug in combination with basic substances, especially with secalin and ergo-chrysin. Jacobi carried out many extensive experiments upon fowls and pregnant animals, the results of which seem to prove that his claims are correct. Grünfeld found that the gangrene of the peripheral parts caused by large doses of sphacelinic acid is due partially to a local action upon the walls of the arterioles, and partially to a direct action on the vasomotor centers, resulting in a narrowing of the caliber of the vessels, followed by the pouring out of a hyaline substance, this condition finally terminating in complete paralysis of the walls of the arterioles; peristalsis of the intestine is markedly increased, ulceration of its walls may occur, and extravasations into the mesentery may also be noted. Sphacelinic acid, because of its direct stimulant action upon the motor centers of the central nervous system, and its local action on the vessels, produces a marked rise in blood-pressure. Also from its action on the motor centers and its local

action on unstriated muscle fiber, it produces tonic contractions of the uterus.

The third constituent, the alkaloid cornutin, is believed by Kobert to be the active constituent desired. But this seems scarcely possible, since the best crude drug contains only a fraction of one per cent. of it. Tanret held cornutin to be a decomposition product of ergotinin, while Jacobi, as already mentioned, believes that we should ascribe the therapeutic value of the drug to the sphacelinic acid contained. Jacobi, however, also thinks that cornutin may in part explain the oxytocic action of ergot. Cornutin possesses very weak basic properties. Like sphacelinic acid, it is only extracted by an alcoholic menstruum. Its salts are somewhat soluble in water. Cornutin is said to be the cause of ergotismus spasmodicus. Mainly because of its irritation upon the medulla, it produces in mammals increased blood-pressure, slowing of the pulse, etc., large doses resulting in tetanic convulsions. However, very small doses, as claimed by Kobert, produce, through action on the motor centers of the lumbar cord, strong clonic contractions of the gravid uterus, simulating those observed during the normal act of parturition. Especially do these results occur when cornutin is administered subcutaneously.

In general we may conclude from what has already been said that the desired action of ergot is due to the pharmacologic properties of the contained sphacelinic acid and cornutin, or their salts. It appears well-nigh impossible to separate these constituents, since the solubilities of both are much alike, but for practical purposes this is of little importance, as they have much the same physiologic action and can be readily separated from the sclerotic acid, which has an opposite action.

With the purpose of obtaining a preparation of ergot which should contain a large percentage of sphacelinic acid and cornutin and as small quantities of sclerotic acid and inert substances as possible, the following experimental work was carried out:

The crude drug employed was carefully standardized by feeding to cocks and noting the reaction manifested by the comb and wattles. The selected drug was ground and divided into a large number of small parcels, which were then percolated with various solvents. The several extracts obtained, and the exhausted drug left in the percolators, were each tested by feeding to fowls, and the results compared. The men-

struum found to produce an extract having the most marked physiologic properties was selected. This menstruum, however, extracts a certain amount of sclerotic acid, which, while it is not harmful (as already stated) for internal administration, was removed from the preparation designed for subcutaneous injection. Since the free acids and the acid salts contained in a fluid extract of the drug are very irritating when administered hypodermically, they were neutralized. The fluid was finally concentrated until one part represented two parts of the crude drug. The finished product was found to be almost entirely non-irritating, but would not keep, owing to the ready decomposition of its constituents. Instead of using alcohol or seeking out some antiseptic which would preserve the fluid, it seemed much more desirable to have the fluid placed in containers holding sufficient for one injection, the filled and sealed containers to be then sterilized. The results were entirely satisfactory. The completed ergot aseptic consists, therefore, of a non-alcoholic fluid preparation of ergot from which the inert substances and ergotinic acid have been removed. The irritating acids and acid salts have been neutralized, the finished product appearing in small glass bulbs, each holding sufficient for one injection. The bulbs, after being filled, and the necks sealed, are then rendered completely sterile by fractional steam sterilization. It is now over a year since the bulbs which I have here were filled, and you see the contained fluid is even now perfectly clear and transparent. A recent test has shown that the contained fluid has retained its physiologic properties apparently unimpaired.

Of far more importance to the physician than the chemic and physical properties is its physiologic action. I have carried out many experiments on various kinds of animals—dogs, cats, rabbits, etc.—which show conclusively that ergot aseptic has the active properties of sphacelinic acid and cornutin. Blood-pressure is raised; peristalsis of the intestine is increased when intravenous injections are administered to dogs and rabbits; gangrene of peripheral parts occurs when it is given to cocks, and expulsion of the contents of the uterus follows when ergot aseptic is administered subcutaneously or internally in proper doses, to pregnant animals at various periods of gestation.

Thus far the clinical results reported by those who have employed it in practise indicate that it is non-irritating and produces

prompt and efficient results. Since I am not engaged in obstetric practise I shall leave the final decision of the therapeutic value of ergot aseptic in the hands of the medical profession at large.

However, before closing I find it incumbent upon myself to again state that it is my opinion after several years' careful testing of ergot by pharmacologic methods, that crude ergot, or its pharmaceutical preparations, should never be employed for medicinal purposes except they be carefully tested for physiologic properties, as the chemist is unable to tell whether this drug and its preparations are active or inert. And for the purpose of testing the crude drug ergot, or any of its pharmaceutical preparations, the reaction noticed in roosters seems to be the most reliable and most readily carried out. The blackened and gangrenous appearances produced in the comb and wattles of fowls is well shown in the accompanying colored plate, which is an exact reproduction of an oil painting made from life.

To my colleague, Mr. J. M. Francis, is due the credit of having overcome the pharmaceutical difficulties in the way of manufacturing ergot aseptic.

#### *THE TREATMENT OF HEMORRHAGE IN TYPHOID FEVER.*

---

BY H. G. McCORMICK, M.D.,  
Williamsport, Pennsylvania.

---

In the treatment of hemorrhage in typhoid fever it has long been taught that opium, morphine and acetate of lead were the remedies to be given in such doses as to paralyze the bowel and bind up their contents in such a way that no movements of the bowels could possibly take place. This treatment was advocated on the theory that the opium would paralyze the vasomotor nerves of the alimentary canal and destroy the peristaltic movement, putting the bowel, as it were, in a splint. The acetate of lead was probably given for the reason (if those who advocated it reasoned) of its astringent effect to bind up what secretions, if any, were acting after the opium had gotten in its work. This plan of treatment was generally pursued in the treatment of all bowel troubles in which diarrhea was present, when the medical profession treated symptoms, rather than diseases—when pathology was almost unknown—before bacteriology had been conceived—when the physiological action of drugs was a myth.

Yet many of the so-called modern works of practise have kept copying these same antiquated plans of treatment of this class of diseases. It certainly should be more respected for its age than for its logic. Emerson says: "Of no use are the men who study to do exactly as was done before, who can never understand that to-day is a new day."

Opium does control peristaltic action, and acetate of lead does bind up the secretions, but do you want to produce these conditions in a case of hemorrhage in typhoid fever? What conditions are present when a hemorrhage of sufficient amount to require treatment has occurred? The muscles are relaxed, the heart's action is weakened, and the whole body is depressed. Is it likely, when every other muscle and set of muscles have lost their tone, and from want of nourishment have lost their power of contraction, that the muscular fibers of the intestines have not suffered from the same cause? From the explicit instructions given to put the bowel at rest with opium one would suppose that all the muscular force of the body had suddenly been concentrated in the muscles of the bowel when a hemorrhage occurs in that part of the body. A little thought will convince you that after a hemorrhage the peristaltic action of the bowel is suspended or abolished in proportion to the amount of blood lost and the effect this has produced upon the body as a whole. Is there any necessity for the giving of a drug to overcome a condition which does not exist? In addition to opium not being of any use, it does positive harm. It dries up every secretion of the alimentary canal from the mouth to the anus. The secretion from the liver which is necessary to carry on the process of digestion, and which furnishes to the bowel the best antiseptic, is suppressed; the secretions from the whole glandular system along the route have been dried up; and you must, of necessity, have decomposition of the contents of the bowel—forming gas and poisonous products, which are absorbed into the system, adding to the already serious trouble new complications to combat.

Tympanites is never a favorable symptom in typhoid fever, and this is especially true in cases where hemorrhages have occurred. The hemorrhage was caused by the rupture of a blood-vessel in an ulcer of Peyer's gland. Will you not add to the probability of another hemorrhage by distending that bowel with gas? and if the ulceration has any depth, will you not further add to the danger of the

case by putting sufficient pressure on the bowel to cause perforation and death?

After a hemorrhage has taken place the blood as a rule is not all expelled and part remains in the colon or at the ileocaecal valve. Blood is a fruitful soil for the development of bacterial growth, and if allowed to remain aids in the further development of the poison. Do you think any harm will come to the patient by these clots being washed out? Instead of giving opium or any other drug to bind up the bowels and secretions, I have been in the habit for the past few years of following an entirely opposite course. I give something to move the bowels, generally a saline, and wash out the colon with ice-water. By this plan I clear out the alimentary canal, carry off the clots of blood and whatever other substance there may be—relax all tension upon the bowel—and I have not had much secondary hemorrhage to contend with.

The bowels should always be kept open in typhoid fever. In a discussion of this subject at the last meeting of the American Medical Association, a very prominent physician made the statement on the floor that constipation in typhoid fever was a good thing, and that cases with constipation did better than those with diarrhea. Now I have had a fairly wide experience, yet I have never come across any disease in which constipation was a good condition; and in conversation with a number of physicians who have seen disease in about all its forms and names, not one of them has been able to give me the name of a single disease in which they were willing to say that constipation was a condition to be sought. I have gone to some trouble to consult the works on practise that I have been able to secure, and yet I have not found a single disease in which they were willing to say that constipation was the end to be secured in order that a cure might be effected. That there are mild cases of typhoid fever with constipation any physician who has seen much of this disease will be ready to admit. But are they mild because they have constipation? Is this the cause for their not being severe? Is it not rather a fact that, being mild, there is not a sufficient amount of pathological change taking place in the bowel to cause a diarrhea, and would not these cases be more mild by the bowels being kept open? Are hardened feces a good application to an inflamed and ulcerated bowel? Is there a physician who has a wild enough imagination to make himself believe that

hardened feces are a "God-send" to an inflamed and ulcerated bowel? When will the teaching of such nonsense as this cease?

By the method I have suggested the bowel is kept clean—clean as it can be by the means at our command; the bowel and ulcer are relaxed, no undue pressure is placed upon it; the bowel is at rest, for the hemorrhage has produced this effect, and the patient is given a fair chance to recover.

*THE STUDY AND TREATMENT OF SOME  
SERIOUS DISEASES AND THEIR  
COMPLICATIONS.\**

BY H. A. HARE, M.D.,

Professor of Therapeutics in the Jefferson Medical College of  
Philadelphia.

The most difficult task for an inventor is said to be the discovery of what to invent, and I confess that the most difficult part of my task has been to find a topic or topics which would prove of interest to you. I have decided, however, that the consideration of several subjects will not be inappropriate. None of them will be novel, but all of them have a direct bearing on the daily needs of the physician.

The first of these is the procedure to which has been given the name "washing of the blood." I have practised this method so often with success that I feel it is not resorted to with the frequency which its power for good deserves, and its harmlessness and wide scope for application make it a valuable therapeutic aid. The present plan has been evolved by a gradual process till its usefulness is assured, and its technique is so simple that even the most timid may resort to it with confidence. It may be divided into two types—that in which the blood is washed by the direct injection of a normal saline solution into the blood-vessels, and that in which it is given subcutaneously and absorbed from the tissues by the circulatory system. It is at once evident that the latter method is necessarily much more slow in its effects and much easier in performance than is that of intravenous injection; and again, that it is devoid of any danger which may exist in regard to the injection of an air embolus or of some foreign body capable of plugging a blood-vessel situated perhaps in some vital area; or again, of the introduction into the

blood stream of some material capable of causing infection.

On the other hand, there are certain conditions in which hypodermoclysis is manifestly of no avail, as for example where the system is in such a state of collapse that the processes of absorption do not go on, or where there is general anasarca, or again where the necessity for relief is immediate or pressing. Let me first, however, speak of the states in which I believe these injections are needed. They have been most highly praised by French clinicians in the treatment of the severe toxic symptoms coming on early or late in the course of the acute infectious diseases such as scarlet fever and similar ailments. In these I have not employed them because I have not met with cases needing this plan of treatment. They are also highly commended in the treatment of the toxemias of sepsis as the result of injuries or surgical interference. Here again I cannot speak of their value from the standpoint of actual experience, because I am not in the habit of seeing surgical cases in these states, although I have employed intravenous injections in two cases to which I was called in consultation long after the surgeons had decided that the condition of the patient was hopeless. The first of these was a man suffering from dry gangrene of the toes of one foot, at first thought to be due to Raynaud's disease, then decided to be a senile gangrene, and finally found to be associated with diabetes mellitus. In this instance the patient developed simultaneously a gradually deepening coma with a rapid spread of the gangrenous process to the calf of the leg, where it was a moist gangrene. Within twenty-four hours after the coma began it was so manifest that recovery was impossible with the use of ordinary measures that I decided to do an intravenous injection of normal saline solution, and did so in the ward by the light of a candle and with no better apparatus than an ordinary rubber fountain syringe and a glass tube to fit into the vein. The patient speedily developed a severe rigor, then broke out into a profuse sweat, and when I left him immediately after the operation I told the family he would not survive the night, as his situation seemed most critical. The next noon I was surprised to find him entirely conscious, free from pain, and able to state that he felt very well. The coma, however, returned in the next twenty-four hours; the intravenous injection was not repeated, and he died shortly after. As the patient had become comatose

---

\* Part of the address in Medicine before the Nebraska State Medical Society, Omaha, June, 1898.

primarily in the absence of his wife and family, his return to consciousness was considered by them little short of miraculous, and they were grateful for his ability to give final directions to them.

The second case I have already reported elsewhere. It was that of one of the most noted scientists this country has produced, who after years of prostatic trouble finally died of septicemia arising in his bladder and kidneys. When I saw him in consultation he was manifestly a dying man, and so ill that any surgical interference was impossible. As the only chance of possible temporary arrest of the downward progress of the case an injection was agreed to. Temporary improvement followed its use, but he speedily sank and died.

The most successful case which I have had from the use of this treatment in uremic coma is that of the father of a physician who called me in consultation when partial coma had lasted for over a week. The urine was very scanty, albuminous, and passed involuntarily. The breathing was stertorous and labored; the face dusky and cyanotic. His condition was so grave that all hope of his recovery had been given up, the more so as he had been refused life insurance ten years before because of renal disease. I advised intravenous injection. It was accepted as the only chance, but with the grave doubt of its doing any good. Immediately after the operation the patient had a severe rigor, partly due to the fact that the fluid injected was not warm enough. A profuse sweat now began, and he speedily became conscious. He has entirely recovered in that this occurred nearly eighteen months ago, and he has attended to his affairs since then. The patient seemed to every one who saw him as if raised from the dead.

Any one inclined to be critical may make objections to attributing the saving of this patient's life to this measure, first, because we sometimes see uremic patients make surprising recoveries, and second, because it is undoubtedly a fact that no means we can use can restore a damaged kidney. The reply to this is that damaged kidneys sometimes break down after exposure or other cause, and the patient becomes uremic and dies when if his life could be prolonged the remaining healthy renal cells would recover from their acute disorder to perform their function properly.

I could cite other instances of a character somewhat like that just detailed, but

time forbids. I can only add that in one particular case a man who came under my care semi-conscious after the injection became entirely clear mentally, and volunteered the fact that he was free from headache for the first time in six weeks. Another man found unconscious in his bedroom in a hotel and admitted to my wards absolutely comatose recovered sufficiently after the injection to tell his name and give his brother's name and address before again becoming comatose. On the other hand, I have had cases in which the treatment failed in the sense that no marked improvement occurred, but in every case in which I have used the method there has been some sign of mental clearing up.

I have used the method in one case of diabetic coma without result. The deaths under its use have been numerous simply because the condition of the patient in severe uremia or other intoxication is necessarily one which is followed by fatal results, and in the presence of such hopeless conditions a few lives saved, if only for a short time, is worthy of careful consideration. Increasing experience with this method of intravenous injection has led me to the following conclusions as to the treatment of patients suffering from uremic attacks:

Use hypodermoclysis provided the symptoms are not pressing and there is no trouble with absorption because of edema; when the danger is pressing, or edema is present even in a very slight degree, use intravenous injection.

In a large proportion of cases the patient should be bled, particularly if nervous excitement or convulsions are present or threatened, because this will relieve cerebral congestion, aid in the elimination of toxins, and aid in the absorption of the fluid from the subcutaneous tissues; or if intravenous injections are used, it will make room, so to speak, for the artificial serum. I believe this is of importance, unless the circulation is evidently very feeble from profound debility and anemia.

Again, it is of great importance to aid sweating by the use of the hot pack, using care that heat-stroke is not produced; but this again should not be used unless the patient fails to sweat, nor if he has a feeble heart.

Finally the saline solution should be carefully prepared, and if possible common salt alone should not be employed. The following formula suggested by Locke, of Boston, is prepared in concentrated sterile

form by Parke, Davis & Co., so that one ounce added to a quart of distilled and sterile water makes a solution which will at once fill the vessels, wash the blood, and support the circulation:

Calcium chloride, 0.25 Gm.;  
Potassium chloride, 0.1 Gm.;  
Sodium chloride, 9.0 Gm.;  
Sterilized, distilled or tap water, sufficient to make 1 liter.

The apparatus I have used is made up as follows: A glass container, such as is used for irrigation purposes in antiseptic surgery, is set in a frame, in order that it may stand on a table rather than be hung against the wall. To the bottom of this container is attached four or five feet of red Para rubber hose, and in the end of this rubber hose is inserted a plain glass cannula; a clip is placed upon the hose, in order that the flow may be controlled, and the cannula and tube which have been attached to the blood-vessel are joined to the tube running from the irrigator at the moment when they are both completely filled with liquid, so that no globule of air will be contained in the tube. This is most easily accomplished by tying the cannula in the vein of the arm and then filling it and its attached rubber tubing with some of the saline solution by means of a pipette.

Finally, let me say that I have used hypodermoclysis in hemorrhage in typhoid fever with the most happy results. It is far less disturbing than intravenous injection, the system takes up the liquid as it is required, and syncope disappears. An ordinary hollow needle may be attached to the tube already described for this purpose.

The solution should be warmed to a temperature of about 100° F. The dose ranges from one-half to one liter, and the frequency of the injections varies according to the exigencies of the case.

*The Treatment of Typhoid Fever.*—This commonplace title is nevertheless one which will interest those physicians who come in contact with this malady. That the body of the profession are not satisfied with the methods generally employed is proved by the numerous so-called plans of treatment and by the fact that these plans often wander far afield from the correct ideas of advanced pathologists as to the causes and morbid anatomy of this disease. Nor is this continual presentation of new plans of treatment due solely to this cause, for it also arises from the fact that on the one hand a

physician discouraged by a high mortality among his typhoid fever patients goes on a still hunt for new methods, or more commonly has a series of cases of mild infection which recover under the new management and are credited to it, when in reality the recovery is dependent upon the benign character of the attack.

It is not my intention to discuss the use of the various plans of treatment which have been brought forward. Only one of these will be presented for consideration, namely, that by the Brand method, which possesses an indorsement in the way of statistics that cannot be equaled by statistics collected in regard to any other plan. Very extraordinary results are claimed for it, and without doubt its value is great, for it certainly modifies many of the most alarming symptoms and the very symptoms which it is difficult to combat under other methods of therapy. Thus it is rare to meet with the advanced nervous exhaustion, the subsultus tendinum, and the muttering delirium in patients who are properly bathed, and circulatory disorder both local and general are not generally met with. Local congestions do not occur, delirium is put aside, and renal and dermal secretion is maintained. All these things are most desirable, and when it is found that the death-rate is also decreased it is not to be wondered at that there are physicians here and abroad who believe that in the Brand bath a panacea for this malady is at hand. It is, however, an old story with the medical profession that plans of treatment are lauded to the skies, remain popular for a given space of time, and then find the level of their real value. The very enthusiasm of the advocate speedily produces a large number of statistical reports from which the more conservative members of the profession may derive information, and often by the excesses of enthusiasm a plan is finally regarded by the body medical as lacking when in reality it is competent if used properly. The course of any new method of therapy is therefore a curve resembling some temperature charts; at first it rises to a dangerous height, then by reason of its primary violence sinks to a point below its ordinary or normal range, and then as the conditions are readjusted it rises to its proper level, along which it runs its course. It is while it is on this normal level that we can resort to a new plan with safety, for now it is possible to understand how it does good, and to grasp its limitations. The primary rise attracts analytical attention

and there is speedily a definite estimation of real value.

In an article recently published in the THERAPEUTIC GAZETTE myself and Holder have shown that the mortality of typhoid fever is decreasing in all parts of the world, a fact also pointed out still more recently in the editorial columns of the *Journal of the American Medical Association*. While it is true that in certain local epidemics the mortality approaches its old severity of about twenty-five per cent., it is a fact that the general average under every form of treatment is about nineteen per cent. at the most, and very often only eight per cent. Again, it is well pointed out by myself and Holder that good nursing and the avoidance of treatment, except for the purpose of modifying the severity of the malady, result in a marked reduction in the mortality. It is important therefore to deduct from the credit given to the Brand bath the important fact that the mortality is decreasing and that the attentive nursing associated with the bath is effective.

These facts are not adduced for the purpose of encouraging those who have not the courage to resort to the bath treatment, but rather that we may obtain definite views as to precisely how useful the bath is. It is not possible in this country to obtain the low death-rate reached by Brand in German Military Hospitals in times of peace, when everything favors any rational plan of treatment. As a matter of fact the experience of physicians to general hospitals all over the world shows that the death-rate is between seven and eight per cent. under the Brand method, and it would seem probable that the saving of life caused by the use of the bath in itself equals about two or three per cent. The saving of three out of every hundred patients would therefore seem in itself to be a trophy well earned by the tubbing plan of treatment, and no one who is acquainted with the statistics of this method or the clinical character of the cases can fail to gladly credit it with this benefit. Cabot, of Boston, has well said in a recent paper that the fault with all definite plans of treatment is that they are supposed by their followers to be the best, and therefore the physician does not look for anything better or for any modification which will remove faults and still possess all the advantages.

It would seem, therefore, that the faults should be first pointed out, for the manifest

advantages have already been discussed. The first fault is in one sense theoretical, in another practical, namely, that no routine method of treatment is rational, for the skilful physician knows that every case should be a law unto itself. In other words, on the face of it, any plan which professes to be of value for all cases does not exist as a fact. When a universal plan of treatment is developed the skill of the physician will no longer be of any service. There must of necessity be states in which the bath is all-powerful for good, and others in which many conditions distinctly contraindicate it. Such conditions may be great cardiac feebleness, the advance of the disease to such a point before the patient comes under observation that his system is too feeble to react to the bath, and the presence of hemorrhage or perforation.

Another disadvantage in the routine use of the bath at 70° is the fact that we are subjecting the patient to a severe measure when perhaps another milder one will do, and it is the duty of the physician not only to prescribe a mode of treatment but to see to it that it suits the needs of his patient.

Before we can decide what cases need to be tubbed it is necessary that we understand the physiological effects of the bath. Unfortunately, very few of those who use the routine bath method do so with clear ideas of how it acts, and no one in this country so far as we know has ever taken the trouble to study with care the effects produced upon the physiological processes in the body by the full bath. One of the eminent therapists in this country has recently expressed his belief that the good derived from the bath is solely due to the reduction of fever. On the contrary, those who have used the bath and have made its study a constant object of observation have again and again asserted most positively that the fall of temperature is by no means the most efficient function of the bath, and they are unanimously agreed that its chief function is to produce reaction or the reflex and direct effects following the application of cold to the skin. These effects are most valuable and important.

The general temperature is often not much affected by the bath and Baruch states he has often seen the mouth temperature after a bath of 65° in typhoid fever reduced to normal while the rectal temperature was two degrees above normal. This is also stated by Liebermeister (*Handbuch der Path. und Therapie des Fiebers*, p. 102).

REMARKS ON THE SYMPTATOLOGY  
AND THERAPEUTICS OF ARTERIAL  
DEGENERATION.\*

BY JOSEPH COLLINS, M.D., OF NEW YORK,  
Professor of Nervous and Mental Diseases in the Post-  
Graduate Medical School; Neurologist to  
the City Hospital.

The writer appreciates the indefiniteness of the title arterial degeneration, but he is unable to encompass the remarks which he desires to make under any other single caption. If the morbid anatomy or mode of development of vascular degeneration were under discussion it would not be difficult to consider the subject in the classical, and at the same time logical, way. But it is not my object to discuss the subject from the standpoint of the master, but rather to put before you for your consideration some ideas, or fancies, concerning the pathogenesis of certain varieties of arterial degeneration which seem to be more plausible the longer I ponder them. In addition, I wish to relate a few clinical histories which shall go to show that although symptomatic manifestations of this morbid condition are extremely disparate, recognition of the underlying disease is the *sine qua non* of their successful treatment. Finally I desire to emphasize the necessity of early, persistent and rational treatment. A word of apology might be appropriate for reading a paper on arterial degeneration before a neurological society, but as I am one of those who look upon neurological practise as a very important part of internal medicine, I shall not offer it.

The manner in which I shall attack the subject will be quite the reverse of the plan usually employed when writing on a given subject or disease. I propose to point out that as yet vascular degeneration, using the term in the broadest sense, is devoid of anything like a definite symptomatology. It is for this reason that separate and individual consideration of it is not often given in text-books on the practise of medicine, on neurology, and on applied therapeutics. The clinical features of vascular degeneration vary so enormously in different cases that the phenomena in many instances are supposed to constitute definite diseases, which are allotted individual description in our text-books, such for example as chronic contracted kidney, vertigo, encephalomalacia, etc. Viewed from a pathological standpoint

there seems to be more well defined convictions as to the status of vascular degenerations. Varieties have been described, associated with certain diseases, such as syphilis and tuberculosis, while others have been allotted the designation "premature vascular senility." The pathology of so-called atheroma of the blood-vessels is as little understood to-day as it was a generation ago, albeit the morbid anatomy of the condition is very well known. The pathological state known as arterial sclerosis, or arterio-capillary fibrosis, still offers much difficulty in its pathological interpretation.

I shall not attempt to say anything of syphilitic degeneration of the blood-vessels, which is almost always an endarteritis, except those cases in which the degeneration is dependent upon gummatous infiltration of the vessel wall, nor shall I speak of atheromatous changes incident to senility.

The theories that have so far been proposed to explain arterio-capillary fibrosis are all of them insufficient, because we continually encounter cases which cannot be interpreted according to any of them. One of the most powerful factors in the genesis of the disorder is a something which we call hereditary influence—a tendency for those who have functional disease of any kind to endow their progeny with the susceptibility to develop similar or dissimilar ailments. What the inherent shortcoming is cannot be stated positively, but I venture to believe that it will some day be found to stand in definite relationship to that system of the body which presides over the growth, the development, and the full maturation of the body and all its tissues, viz., the sympathetic nervous system. I cannot state the many facts and analogies that support this view, as Dr. Joseph Fraenkel and myself intend to do in a forthcoming publication, but it has seemed necessary to make statement of this belief, in order to make my views concerning the pathogenesis of arterio-capillary fibrosis more clear.

The immediate causation of arterio-capillary fibrosis is attributed to gout, rheumatism, alcoholism, indigestion, exposure, overwork, enervating, depraving influences and environment, and to many other analogous factors. Every one admits that some of these conditions are oftentimes to be observed in the antecedent history of a patient who develops arterio-capillary fibrosis. But none of them need be present. In fact, oftentimes search for any of them will be in vain. It is

\* Read before the Brooklyn Neurological Society, April, 1898.

possible that sex variations in the liability to, and the use of, these injurious agencies may explain the fact that the disease is enormously more common in males than in females, and very much more common in degenerate races such as the negro than in those that have reached a more advanced evolutionary stage. But the fact is this selective variation in races and sexes needs far more comprehensive handling than it has heretofore received.

Man is as old as his vessels and woman is as old as she looks is more truthful than poetic. If one observes those about him in the street, in the railway car, in the church or the theater, he cannot but be impressed by the fact that for every woman he sees who has such suggestive marks of arterial sclerosis as tortuous, rigid-looking temporals, features expressive of senility at variance with apparent years, a recession of the fronto-temporal hair line indicating the decession of allotted years, etc.—that for every woman he sees with such signatures he will see ten men. Casual observations thus made are fully borne out by the experience of the bedside and the consulting-room. Why should this be? Is it because men work harder, drink harder, play harder and take less intelligent pleasure and relaxation than their wives and sisters? It may be, but when we look at the matter carefully it verily does not seem that such an answer encompasses the explanation. We know of countries wherein the hardest physical labor is done by women, and of other countries in which riotous living, eating, drinking and indulging is only vouchsafed in part to the male, and yet arterio-capillary fibrosis apparently spares the woman in the case. The explanation of this I shall leave for you to suggest; it surely is worthy of careful thought.

It is not sufficiently recognized that the vast majority of the diseases which the neurologist encounters, aside from diseases of an infectious nature, are of two kinds—those conditioned by functional perversion of the vascular system, and those caused by degeneration of the vascular system. That this is a fact, every worker in the field of clinical neurology will admit. The moral to be drawn from this is to search for the *modus operandi* by which these conditions are brought about. I venture to think that if this is done a clearer conception will be had of many diseases, especially functional ones, that are to-day considered very obscure.

I shall not say anything this evening of

functional perversions of the vascular system which are not accompanied by changes in the blood-vessels, but shall limit my remarks principally to arterio-capillary-fibrosis.

The theory which seems to me most satisfactory in explaining the pathogenesis of arterio-capillary fibrosis is one that looks upon it as a disorder of the sympathetic nervous system, the vegetative nervous system. We know a great deal about the development and the anatomy of this very important part of the body; we have some information regarding its functions; but we know nothing, or next to nothing, of the phenomena that result from its disease. We are inclined to believe that certain neuroses, dermatoses and trophic states are dependent upon its depravity and disease, but aside from this no rational conception of its functional perversion or organic disease has yet been offered. We find ourselves, therefore, in the very anomalous position of knowing that the sympathetic nervous system is the most important tissue or system of the body, and yet we are entirely ignorant of the conditions that result when injurious factors, single or manifold, interfere with its proper working. Pathologists have neglected it with seeming studious intent. For instance, in those diseases in which there cannot be the slightest doubt that the sympathetic nervous system is the seat of the morbid influence, workers in the field of morbid anatomy have gone through the various tissues of the body with great diligence, and commendable care, but they have left the vegetative nervous system as if it were something apart from the rest of the body and not susceptible to injurious influences. We may cite in proof of this the status of the morbid anatomy of such diseases as diabetes, Addison's disease, and Graves' disease—diseases which time will prove, I venture to believe, to be as closely dependent upon lesion of certain parts of the sympathetic nervous system as typhoid fever is known to be dependent upon a specific form of ulceration of the glands in the small intestines.

One of the most important functions of the sympathetic nervous system is to innervate the cardio-vascular system. The next most important function is to supply the glandular system. These two systems, being extremely interdependent and harmonious, when one is disordered the other is bound to be deranged, and *vice versa*. It is perhaps needless to say that no other kind of nerve fibers, save those

of this system, go to these tissues. The factors that have been enumerated as causative of arterial degeneration, arterio-capillary fibrosis, such as gout, rheumatism, alcohol, indigestion, overwork, and the like, are all operative through the sympathetic nervous system, and the changes which they cause in the blood-vessels are conditioned by perversions of this system. It is an evidence of concentric limitation of the intellectual field to search for the pathogenesis of arterial sclerosis in the products which remain in the system, the result of incomplete metabolism or of defective elimination, and at the same time to neglect the mechanism by which these conditions are brought about. To illustrate my meaning, within the memory of the most recent of us the advent of the physiological chemist, the physician versed in the mysteries of the laboratory, has been hailed as the coming of the interpreter of what are called humoral and diathetic diseases. The hope has been held out that his investigations would illumine the obscurity of their development, and that he would point the way for their prevention. Unfortunately, we are yet awaiting the realization, although he has been studiously at work for a score or more of years. True it is that he has shown, after laborious investigations on the excreta, that certain products of metabolism, particularly of nitrogenous metabolism, are deficient or overabundant in the excreta. In conjunction with the clinicists he has observed that certain outbreaks of disease may coincide with one or the other of these abnormal states, and he jumps at the conclusion of cause and effect, without taking into consideration that these are but incidents and that the antecedents of such defective metabolism are to be sought in that system which regulates normal metabolic changes, preserves its equilibrium, and manifests changes in the secreta and the excreta when injurious influences pervert its function. If we take, for instance, the enormous amount of work that has been done on what is fallaciously called intestinal sepsis, or intestinal antisepsis, and the system of therapy that has sprung up as a result and ask ourselves, What does it all amount to, what has really been gained? the answer must be, Practically nothing. And why? It is because we have not taken a sufficiently broad and comprehensive review of the forces antecedent to pathological fermentation, to incomplete metabolism, to defective elimination, to partial oxidation, and the like. In short, it is because we have not taken the

sympathetic nervous system, the great conditioner of secretion, of excretion, of circulation, and of oxidation, into the question.

A similar arraignment may be made of the hiatus in our knowledge of the pathogenesis of arterial degeneration. The causation of acute inflammation of the blood-vessels, arteritis, and phlebitis, or of chronic inflammation of the blood-vessels, has offered no considerable difficulty, because their causation has been searched for in the blood and in fact are operating directly on the blood-vessels. But non-inflammatory diseases of the blood-vessels are not caused by diseases of the blood, although they are oftentimes accompanied by morbid blood changes, secondary to and coincident with diseases of the blood-vessels. Degenerative changes in the vessels, unless sequential to inflammatory changes, are of slow development, they are not uniform in their distribution, they occur simultaneously in far-apart regions of the body, and they are likely to attack the blood-vessels of organs that are highly functionable. These facts indicate that such degeneration is the resultant of a unity of causation, and search as we may for such unity of causation, we can only find it in the sympathetic nervous system. If we take for instance the relationship of arterio-capillary fibrosis to rheumatism, to gout, to alcoholism—in short, to conditions that cause perversions of metabolism—and attempt to interpret them on any other basis than that which posits primary disorder of the sympathetic nervous system and consequent secondary manifestation of disorder in the blood-vessels, we shall early encounter insuperable obstacles. We cannot, for instance, believe that the physical dissociation of the components of the blood which is evidently at the basis of rheumatism, or the chemical changes in the blood which form the apparent basis of gout, or the presence of ethereal sulphates, uric acid, etc., which are attendant upon chronic intestinal indigestion, exercise a mechanical and irritative influence upon the blood-vessel. If they did, we must needs have a generalized desquamation and endothelial proliferation throughout the vascular system, the same as results in the tubules of the kidney when substances irritant to that organ are excreted, and the tunica intima would be the part primarily diseased; but such is not the case, for in every instance the primary changes are in the media and adventitia.

We can, however, readily see how these dissociated changes in the blood which are

at the basis of gout and rheumatism, these evidences of defective metabolism and excretion, which occur in chronic indigestion, etc., are immediately conditioned by disorder of the sympathetic nervous system, because this system presides over secretion, over excretion, over metabolism, and over vascular regulation. When the chronic intoxicants are present sufficiently to cause any of the diseases enumerated, or when alcohol so exercises its pernicious effect upon the sympathetic system as to overthrow its functional balance, nutritional changes will begin to be manifest in the blood-vessels through the medium of the vasa vasorum supplied by the sympathetic nervous system, and these changes in the media, in the adventitia, and eventually in the intima, constitute the morbid anatomy of arterio-capillary fibrosis.

In the same way are to be explained those cases which result secondary to renal disease, a comparatively small proportion of cases, it must be said, occurring in this way. The poisonous matter which should be excreted by the renal organs remains in the system, and its peccant activity is manifest on the sympathetic system of nerves and through it on the blood-vessels. In other instances, the retained noxious matter is most operative on the cerebro-spinal system to cause the well known symptoms of acute or chronic uremia.

And now, to turn to some of the symptomatic features of arterial sclerosis or arterial degeneration, I shall cite a few cases to show that the clinical phenomena may be absolutely different in one case than in another. In other words, unlike other tissues of the body, which when diseased call forth complexes of symptoms having definite symptomatic foundations which are nearly constant, the symptoms caused by arterio-capillary fibrosis are extremely disparate. The first case that I shall cite is one that may be labeled "lumbago," if you please. This is a term that has never had any definite significance attached to it, but nevertheless it has risen to the dignity of separate consideration in medical journals and in systematic treatises.

The patient, referred by Dr. St. John Roosa, is a young man, of temperate habits, who is happily married and contented with his profession and outlook in life. He has not had syphilis, nor has he been addicted to excesses. He complained of attacks of severe pain in the back, which came on every month or two, sometimes at longer intervals, sometimes at shorter, and which necessitated

his remaining under cover for from ten days to two weeks. When the attack first came on the pain in the small of the back was so severe that he could not move. The pain after a short time tended to irradiate down the thighs to the knees. Sometimes it came like a stitch or crick, beginning in the center and radiating out toward the hips, leaving a very sore feeling in its wake. These attacks had weakened him considerably, and he felt the necessity for some sort of a brace or corset to help pull him together. He was of good physique, but of sallow complexion, and somewhat emaciated, and he complained that his strength was very indifferent. His first attack of pain of this character dates back to about five years ago, and apparently followed considerable excitement, overexertion, and exposure. A boat in which he was fishing off the banks having sprung a leak, it was necessary to bale for a number of hours until they were rescued. Some time after this he was treated for an attack of nervous prostration, by a physician of Boston. He has received a great deal of medication in the last few years, and before coming to me he had the luck to escape from a surgeon who had been treating him for a number of months and who finally decided that he would open him up and make captive his kidney; this gentleman having apparently read something of the symptom-complex known as Glenard's disease. Examination showed no departures from normal worthy of remark, save resistant arteries which would not compress completely under the finger, an accentuated aortic sound, and the pallor already spoken of. The hair is scant, and that which remains is of quite a different character to the natural hair. The patient said it was not hair but fur, and to the touch it was much like cat's fur. There was a well defined zone of marginal eczema around the hair line, and the finger- and toe-nails showed decided trophic changes. An examination of the urine showed it to be diminished in quantity, the average being from thirty-five to forty-five ounces, a relative excess of urea, a number of hyaline casts, but no blood, no albumen, no pus, no epithelia. Repeated examination of the urine, day after day, and month after month, never revealed the slightest trace of albumen nor of epithelium. The patient was put upon a diet consisting largely of butter-milk and cream, skim milk, the proteids diminished, the hydrocarbons and carbohydrates tentatively increased, and instructed

to take large quantities of water. Medically, he was given in the beginning diuretin in ten-grain doses until the quantity of urine was increased, and then put upon iodide of potash and Basham's mixture. Careful attention was given to the excretory organs, the sympathetic nervous system was stimulated by rain baths, and the result is that the patient has gained twelve pounds in weight and has not had an attack of so-called lumbago since he first came under observation, now more than seven months. The general health has increased proportionately. Occasionally a hyaline cast has been found in the urine, but aside from that it is quite normal. The blood-vessels give a materially different impulse to the finger and show a different sphygmographic tracing than they did in the beginning, and the aortic sound is by no means so accentuated.

I anticipate that some of you may say that this is a case of Bright's disease, and I shall be inclined to agree with such a one if he will point out wherein it agrees with the varieties of disease of the kidney that we are taught to recognize under that name. Until then I shall look upon it as a beginning wide-spread vascular degeneration conditioned immediately by disordered nutrition dependent upon perverted function of the sympathetic system, occurring in a comparatively young man, and that his recovery is an evidence of the recuperability of such blood-vessels when the lesion is not advanced.

The second case that I shall recite is a much more conventional type of arterial degeneration. The patient, a man forty-eight years old, was seen with Dr. J. C. Lynch, of Bridgeport. His complaint was of "dizziness in the head." For the past year he has had occasional attacks of vertigo, during which he would feel as if he were going to fall forward, and he thinks that for a moment he would be unconscious. For the past two or three years it had been noted by himself and by others that there was a change coming over his disposition, his memory, his ambition, and his courage. Although by no means a sluggard or non-observant, he had lost interest in things and in people very decidedly during this time, and physical strength had become impaired. About seven weeks before I saw him he began to have attacks of giddiness very frequently, so that he was obliged to go to bed. The vertiginous sensations were of falling and of rocking side-wise. They would last for about ten minutes, and as soon as they disappeared he felt very

hungry. It was particularly remarked that the attacks of vertigo were likely to come on when the head was much extended on the pillow. In addition to vertigo, he has had a good deal of frontal headache, flushing of the face, nausea, cold extremities, sluggish action of the intestines, and a tendency of the abdomen to balloon without apparent indigestion. During the past year he has had a number of crying spells, but was more often in a state of indifference than of depression. Examination showed a sluggish condition of the pupils, a fine tremor of the tongue and of the extremities, and over-excitability knee-jerks. The temporal arteries were conspicuous and sinuous, they rolled beneath the finger, and the walls of the radial artery were discernibly sclerotic to the touch. The second sound of the heart was loud and booming, the first sound short and jerky. Aside from this the visceral organs were normal. Examination of the urine showed no abnormality, save an excessive secretion averaging from sixty to seventy ounces, and a comparatively low specific gravity, varying from 1.009 to 1.013. A few days before I saw him his physician had placed him on an operating table to search for hemorrhoids, of which he complained. The examination caused him pain, and he hung the head over the side of the table. In a few minutes he was taken with a universal convulsion very similar to an ordinary epileptic attack, which lasted about a minute. Since that time there has been no repetition of this, nor was it apparently attended by any evil consequence. His physician reports that treatment consisting of absence from business, a uniform milk diet, regulation and limitation of physical exercise, the administration of a mixture of nitroglycerin and iodide of soda, and an absorbable preparation of iron, has caused the attacks of vertigo to cease and a bettering of the patient's general condition.

The interpretation which I put upon the epileptiform attack is that this patient, with advanced arterial sclerosis, put his body into such a position that an undue amount of blood was sent to the cerebral blood-vessels, which caused their dilatation. The process of disease in the vessels having destroyed their elasticity, the return to their normal caliber was impossible, and the result was a passive congestion, which was manifest externally by symptoms of motor irritation, and these subsided only when the patient was brought into a sitting posture, the return to normal cali-

ber of the blood-vessels being assisted by gravity.

A third case which I shall cite as an evidence of arterio-capillary fibrosis is one that may be diagnosed as acroparesthesia, a condition which was formerly described by Putnam, by Dana, and by the writer, as the paresthetic neurosis, but which is now usually designated by the term above mentioned, a sufficiently fitting one, meaning as it does perverted sensation of the extremities. The patient was a woman of fifty, who has worked hard all her life, and who has but recently finished with the menopause. She complained of giddiness, and of vertical headache, but the principal reason for coming to the clinic was that her hands got unwieldy and numb, less dextrous and agile. She could not sew, and was prevented from doing any work save that of the grossest character. Very often the hands and feet were the seat of tingling sensations, feeling of "pins and needles," and this was particularly liable to occur in the early morning, it being so severe at this time that it usually awakened her. In addition she complained of flatulency, of constipation, of impaired strength and ambition, of cold extremities, and of occasional attacks of profuse perspiration, which weakened her. Examination showed a high-tension pulse with weak heart beat, thickened arterial walls, an extremely accentuated aortic sound, tortuous temporals, and the general vascular conditions that constitute the signature, arterio-capillary fibrosis. She improved under the same plan of treatment that was advised for the previous patient, except in this case *cascara sagrada* and *belladonna* were added to the list.

The fourth case that I shall cite is one that had given some difficulty in its interpretation, and I shall be glad to hear if any of you have encountered similar cases in your practice. The patient was a manufacturer, sixty-four years old, who has been abstemious in everything save work. He has labored long and persistently to shear the sheep with the golden fleece, but, notwithstanding, he retained a commendable degree of bodily vigor and mental health. He denied venereal disease of any kind, and he is married, but childless. Until about three months before I saw him with his physician he had been in his customary health, but had been harassed somewhat by business cares. It was remarked that he did not disport himself as formerly; that he was preoccupied and less communica-

tive, and inclined to be depressed and easily irritated. He slept badly and lost flesh progressively, so that at the end of about ten weeks his weight had fallen off thirty-five pounds, and his apparent age had increased about ten years. Accompanying these were perversity of appetite, constipation, and excessive secretion of urine. Although apparently of sound mind, of fair memory and reasoning capacity, he began to have strange fears and obsessions concerning his business and his personal safety. These were in a measure undefinable, but he often stated that he would not be allowed to remain home long; that the city or his creditors would have him sent away, although he would give no explanation of these statements. At such times his demeanor was that of one who had indulged in some transaction that did not redound to his credit and which he desired to keep to himself. These false beliefs were in no way systematized, nor could he give any reason for their possession. He remained at home, fearful of going out, and day by day seemed to get a little further removed from bodily health, the principal symptoms being sleeplessness, restlessness, irritability, groundless fears, and progressive loss of flesh, all without apparent cause. Examination revealed, in addition to the impaired nutrition and its concomitants, loss of kneejerks, contracted pupils which did not react to light and shadow, and very little in accommodation, and fine tremor of the extremities. There were no sensory disturbances, no dereliction of the sphincters, and none of the associated symptoms of *tabes*, or of the somatic and physical conditions that go to make up the signature, general paresis. The evidences of arterial degeneration were striking in the blood-vessels, in the peripheral circulation, in the heart, and in the urine. Treatment directed toward the relief of this degeneration has been followed by improvement, but he has not been under treatment sufficiently long to warrant a statement of how complete his reparation will be.

This is a type of case that physicians look in vain to their text-books for recognition and elucidation. The complex of symptoms do not fit in with any of the described diseases. The case is not one of *tabes* nor of general paresis, although it has a number of the important symptoms and accompaniments of these two diseases; but the general features of the case are so unlike these diseases that no one would make the mistake of allotting it to either. If one chooses he may call it

neurasthenia of a grave type or a variety of melancholia, and dependent upon organic changes in the vessels, but such baptismal indulgence does not help us any in interpreting the nature and genesis of the disease nor in directing the treatment. The important point, I venture to state, is the recognition of the fact that we are dealing with a disease of the vegetative system of the body which is manifested principally in the blood-vessels, and that the treatment of the mental and nervous symptoms must be through this system, and these tissues.

The next, and last, case to which I shall refer is one that has interested me very much, first because of the effect of treatment, and second, because it has seemed to me an important contribution to aphasia. The findings of the case have been summarized in my recent book, "The Genesis and Dissolution of the Faculty of Speech" (The Macmillan Company, New York, 1898).

Mrs. X., a widow, sixty-three years old, the mother of eight children, has had a vigorous, active life, free from ill health, save that twelve years ago she suffered severely from attacks of renal calculi. During the past year or two she has complained of indigestion and more recently of a dull, aching sensation in the back of the head and neck, with occasional attacks of very severe pain in the left temple. For a few weeks previous to the beginning of her present symptoms she suffered from insomnia, from irritability, nervousness, and forgetfulness. Her son, a physician, gives the following account of the onset of her aphasic symptoms: One week before consulting me she discovered, while making a call, that her speech had become, without warning, very much embarrassed. She could not finish the sentence that she had started to speak. She forgot what she wanted to say. She chafed under this impotence and got very much excited. She returned home in a street car, and was much astonished to discover that on looking at the signs with which the cars are lined that she was quite unable to comprehend their signification. She could see the letters and words, she knew that they were letters and words, but they conveyed no meaning to her. When she got home she tried to tell her family about her disability, but was able to say only a few words, and these were entirely disconnected. After trying to speak for a time she became excited and began to cry. On the following day, when she awakened, she could say only "Yes" or "No," but as the

day wore on her vocabulary became somewhat larger. It was particularly remarked that when she was excited or very emotional sometimes words would flow out of her mouth in an astonishing manner. From that time until I saw her there had not been very much change in her capacity for speech production.

The following is a stenographic report of the examination to determine disorder of voluntary speech. In response to the request to tell me all that she could concerning the onset and course of her symptoms, she said:

"Well, mem-mem—three weeks, m-m-em—feel-m-em-em—sometimes [prolonged pause, seems to be thinking] couldn't thought—no thought—forget—but—eh—last Friday [another prolonged pause] am—no—noticed they—I couldn't—eh—I—[prolonged pause] I couldn't tell, am, I don't, I can't, can't express [explosively]. I can't tell—I cannot [points to her head and looks weary]. It seems, I can't, last Monday, con-con-nects—sentence, two or three words—gone. Was—gone, blank, didn't know. Can't think, was gone, forget—forget everything. Couldn't, couldn't, can't."

To test her capacity to repeat, I asked her to say after me, "I stood on the bridge at midnight." Her reply was:

"I stood—the—night," said with great effort, and with apparent endeavor to repeat each word as quickly as they fell from my lips.

"Still sits the schoolhouse by the road?"

"Forget—yes—the—the s' s' s' forget—road."

"Waterloo was a battle of the first class, won by a captain of the second."

"The bat-tle, ah, me, ah me, ah."

It is particularly noticeable that when I speak she endeavors to say the words after me very rapidly one word after another, but it is quite impossible for her to repeat more than a word or two. The patient is an English lady who formerly was able to speak German very fluently, but when I recite the first verse of Schiller's "Bell," beginning, "Fest gemauert in der Erde," etc., she is not able to repeat a word of it. I then ask her to repeat the Lord's Prayer. She assures me by nod of the head that she cannot do so, but when encouraged to try she says: "Fa' a' ther—our fa—" [gets excited and I believe tries to convey to me that she was unable to repeat it last evening]. I then asked her to say it to herself. She again indicates that it is entirely impossible. I ask her if it is impossible, and she says "Yes."

It is interesting to note that when I encourage her to say it to herself after I have told her that I am going to say it in my internal language to determine if we reach the end simultaneously, she adopts the conventional attitude and manner, probably thinking that they will prompt the recalcitrant words, but all to no purpose. She is quite unable to read, either in a loud voice or to herself, although she can say a word of what she reads here and there, but words and sentences convey no meaning to her. She takes up the newspaper, cons it carefully, then puts it down with an expression of dissatisfaction and disgust. In other words, there are manifest verbal blindness and profound alteration of mental images. There is no trace of hemianopsia.

When I request the patient to write her name, she does so promptly. When I ask her to write the name of her son, she does so; likewise the street and number where she resides. She is absolutely unable to write spontaneously. Her capacity to write from dictation is tested by asking her to write, "When in the course of human events," but she is absolutely unable to do so. The only word that is produced after numerous attempts and repetitions of the sentence is the word "When."

Writing from copy is done without trace of hesitation or error; and when she is asked to copy printed letters in writing she does so with great readiness. She comprehends spoken speech, but oftentimes it is necessary to repeat before the meaning of what is said fully dawns upon her. In other words, although there is no word deafness, there seems to be some difficulty in calling up auditory images quickly and readily.

She has no trace of hemiplegia, unless we call a slight asymmetry of the angles of the mouth an indication of defective cortical innervation, as the right angle of the mouth seems to be a trifle lower than the left. There is no ataxia or incoordination of the extremities; the knee-jerks are lively and of equal intensity on both sides; the pupils react to light and shadow; there is no tone deafness or object blindness. The urine contains albumen and casts; the pulse is regular; the arteries are hard and incompressible, and the second sound of the heart is very much accentuated. In other words, she has extensive arterio-capillary fibrosis.

The interpretation which I put upon the case is as follows: Pathological diagnosis—general arterio-capillary fibrosis, with conse-

quent slight encephalomalacia of Broca's convolution. Clinical diagnosis—true cortical motor aphasia, articulatory kinesthetic aphasia. I need not remark that the elicitable symptoms parallelize in every detail those typical of this form of aphasia. The chief deficiency of internal language seems to be an inability to evoke the articulatory kinesthetic images of the words, and this constitutes a gap in the circuit of internal-speech impulses. No more illustrative case could be cited to show that spontaneous writing and writing from dictation are disordered commensurately with voluntary speech in true cortical aphasia. Moreover, the case shows with uncommon clearness that a striking degree of verbal blindness occurs with cortical motor aphasia.

The patient has improved very materially under the same plan of treatment that was given in the previous cases.

And now, to turn more directly to the treatment of this obscure but widely prevalent disorder. I have little that is new to offer, but it may be of some advantage to make a statement of personal experience, that one may determine if it tallies with that of others. No one can have had much to do with cases of this sort without reaching the conclusion that their successful treatment must needs be almost as individualized as we have seen their causation to be. Although there are certain underlying principles which guide us in the application of medicinal, hygienic and dietetic measures, which are so sanctified by long experience that no one thinks of doubting their applicability, nevertheless they cannot be applied without discrimination and judgment. All cases are bettered if the excretory avenues of the body are kept scrupulously free and functionally active. The diet should be of the simplest, most easily digestible, and most nutritious. This is a necessity that is scarcely ever carried out, even though it be enjoined, for the patient with arterial sclerosis cannot be persuaded in the beginning of the gravity of his disease. It is not improbable that arterio-capillary fibrosis would not be so uniformly progressive were it not for the hesitancy of physicians in diagnosing it before it has produced symptoms that threaten the duration of life, and the fact that patients will not assume the necessary attitude toward regimen, hygienic and medicinal measures and persist in them. If the cases are seen sufficiently early, the treatment should be directed toward the maintenance of the functions of the sympathetic nervous system, par-

ticularly its metabolic and vascular functions. In doing this it may be necessary to retrench the work put upon it; to aid it in doing its work; and to guard against the evil effect that may follow its partial disability. The retrenchment consists of the dietary and hygienic measures already mentioned; the guarding against consequences of disordered sympathetic perversion is sufficiently explicated by what has been said regarding the emunctories; the third indication, namely, that of assisting the sympathetic in carrying through its metabolic and vascular functions, is best met by life in the open air, if possible, by intelligent exercise, and by hydric procedures.

I am well aware that these statements are truisms. I repeat them only because it seems to me that they are not sufficiently often insisted upon in practise; in other words, that an endeavor is made to supplant them by medicines—a fatuous hope.

Of all the hydric procedures that I have found most serviceable, the rain-bath is by far the most important; if the disease process is not far advanced I regard it of great service. Naturally it should not be used in senile cases. It depends upon the vitality and reaction of the patient whether or not he should be first heated somewhat by being wrapped in a hot sheet and blanket, or put in a hot box for a few minutes, with the head exposed, before being put in the circular bath. If his vitality is not very abundant, and his reaction responsive, this heating before the application of the rain-bath will be found to be very salutary.

The question of exercise is one that cannot be decided for even a given case until that case is studied individually and with care. I am inclined to believe that the promotion of metabolism, brought about by mechanical percussion, massage, and the other mechanics of Zander institutes, is of far greater utility than walking, riding, golfing, and the like; and in any case the latter should be indulged in with great moderation. The value of fresh air, of course, is not overlooked, but it has been my experience that patients with arterio-capillary fibrosis do better when they take fresh air without very much exercise with it. For many patients such a plan of treatment as this spoken of will be entirely unfeasible. But here we have to make the same concessions to breadwinners as we do in other diseases that need different environment and change of climate.

The medication of arterio-capillary fibrosis

which physicians rely upon more than anything else, probably, is the administration of iodide of potassium, the nitrites, and iron. No one doubts the very great importance of all these measures, but the mistake should not be made of relying too exclusively upon them. Naturally, the iron favors oxygenation and oxidation. The iodide salts have some action upon the sympathetic nervous system which we in no way understand; and both of these results are sought for in the treatment of this disorder. The question that every one has to decide in administering the iodides and the nitrites is, what salts or preparations are most serviceable and how long shall they be kept up? For instance, after giving nitroglycerin for a month or two months, or even longer, the question arises should it be persisted in, the indications for its use being still present in the increased tension of the pulse? It is my conviction that better results are obtained if the nitroglycerin is interrupted for one week out of every four or thereabouts, and dependence placed in the meantime upon opium to maintain the compressibility and elasticity of the artery. I know that opium increases the systole and raises blood-pressure, and that therefore it is contraindicated in arterio-capillary fibrosis. Nevertheless, it is my experience that in very advanced cases of this condition quite as much, or more, reliance can be placed upon morphine to contribute to the patients' comfort and to the length of their days than on any other single measure.

There are one or two points concerning the administration of the nitrites and the iodides to which I would like to refer. The first is that nitrite of sodium is incomparably more serviceable than nitroglycerin. The most important factor in its favor is the duration of its action. Its physiological effect lasts about four hours, while that of nitroglycerin is from fifteen to twenty minutes. The second point to which I wish to call your attention is that nitroglycerin gives me greatest satisfaction when it is administered in fractional doses—*i.e.*, from  $\frac{1}{100}$  to  $\frac{1}{80}$  of a grain every half hour, or even every fifteen minutes. This dosage is kept up until the desired effects are produced, the quantity being afterward increased or diminished as the needs of the case may make it apparent.

Of the iodide salts, the iodide of soda is by far the most deserving of use in arterio-capillary fibrosis. It has nothing like the tendency to derange the digestive tract that the iodide of potassium has. I prefer to ad-

minister it in milk if the patient can take the latter; if not, any alkaline medium furnishes the most acceptable substitute.

Thus I have been able to offer nothing in the way of therapy that is at all new to you, but in closing I would like to say that to my mind the most important element in the treatment of arterio-capillary fibrosis is the study of the individual case, that one may detect wherein exists the defect of the vegetative system which is gradually undermining the blood-vessels. When its apparent source has been discovered, be it gout or rheumatism or what not, we should not be content in attacking that. The factors antecedent to the apparent cause must needs be eliminated, then the state which we have been speaking of cannot come into being.

---

*CALCULOUS DISEASE, AND THE TREATMENT BEST ADAPTED FOR ITS PREVENTION.*

---

BY H. FOSTER HAZLETT, M.D.,  
Pueblo, Colorado.

---

The results of modern operative procedure for the removal of calculous matter are certainly admirable. These excellent achievements of our craft are themselves a great monument to the triumph of modern surgery, and yet how infinitely preferable would it be to be furnished with the means of restraining the formation of calculi, on the first appearance of evidence that such a contingency is imminent or likely to occur.

I believe there exists a period in the history of the process which leads to the formation of renal or vesical calculus at which it might be possible to prevent the development of a considerable deposit, and hence the necessity for mechanical interference in its removal. For our purpose, it suffices to regard all calculi as generally divided into two classes—those which have a local, and those which have a constitutional, origin. By the term "local" is meant those concretions whose formation depends upon diseased action in the bladder only, and not depending upon constitutional diathesis; and by "constitutional" I mean formed in consequence of a malassimilation which has become more or less inherent in the system. The large majority of renal and vesical calculi are of constitutional origin, and it is to this class we wish to refer in particular. Preventive medicine has little to do with calculous matter of local origin except in a mechanical

way, as for instance the breaking, dissolving and washing away of vesical calculous matter. Mechanical means are of no avail when stones are of constitutional origin, because their component elements are separated from the blood and it is only at this early stage that anything can be of avail.

Now, from available statistics and observation, we know that nineteen out of twenty of such stones have uric acid for their basis, the remaining one in twenty being oxalate of lime; and, less commonly still, there are phosphatic stones which are of constitutional origin also. Reasoning on this premise, the proposition practically resolves itself into the prevention of uric acid deposits.

In our examination of the early history of a case of persisting uric acid formation, we not infrequently see a marked manifestation of hereditary influence. How frequently do we find in tracing up the family history of a uric acid patient that his father had "gravel or stone for the last twenty years of his life." It is not an unusual experience to find a history of gout in connection with the patient with a uric acid stone. Few indeed are the calculous patients with neither gravel nor gout as factors entering into the history of their preceding generations. This hereditary tendency varies in force or strength in different families, but scarcely more than is found in tubercular or cancer diseases. Some persons at thirty years of age show persisting uric acid deposits, others at forty, others not until sixty. Of course, the earlier the age at which it appears, the stronger you may infer the hereditary disposition to be, and the more obstinate, probably, will be its tendency to persist. The first symptom of this condition, usually, is the frequent occurrence of a pink sediment at the bottom of a vessel in which urine has stood. This deposit with its staining propensity is the first thing which excites attention on the part of the patient. This character of urine, passed originally perfectly clear and healthy in tint, soon, upon cooling, becomes turbid and opaque. The lower the external temperature and the smaller the amount of urine passed, the more marked these phenomena seem to be, hence the more frequently to be found during the colder months of winter, when smaller amounts of water and fruits are consumed. The change consists in a deposit of salts from a hot solution as the liquid cools; the deposit being easily redissolved by heating the urine, when it regains also its original transparency. It is the persistence, or at

all events frequency, of occurrence of the above symptoms which taken collectively mean an unduly large production of the mixed urates (urates of soda, potash, lime, etc.), and in time the arrival also of little crystals of uric acid, looking like particles of Cayenne pepper or red brick-dust, at the bottom of the vessel, which denote an undue tendency to produce uric acid, either inherited or acquired. We grant the possibility, indeed the probability, of this being an acquired condition, or the preexistence of an intensified habit; indeed, it is often the result solely of improper diet and regimen.

Let me again insist that this may occasionally happen with the most healthy individuals; and it is only the persistence of the symptoms, without any flagrant errors of diet, which should lead one to suspect it to be a constant condition that requires medication.

We have now followed the complaint up to the formation of Cayenne pepper crystals. This deposit consists mainly of transparent rhomboidal uric acid crystals, and is to be regarded as a pathological change. In healthy urine uric acid exists only in combination, and is not found free, except possibly in the smallest amount (three to ten grains per twenty-four hours), at the moment it is voided. Patients who periodically pass large quantities of this material not infrequently experience pain in the back, or over one hip, with darting pains extending to the groin or testicle, and accompanied perhaps by nausea; and he may then be said to have a mild attack of gravel. Occasionally these symptoms are much exaggerated, and it is then said of the patient that he is passing through the stage denoting the passage of a renal calculus. Have not these patients been the subjects of a "uric-acid storm?"—to use the words of Sir Henry Thompson. These phenomena become more frequent or severe, unless the patient does something to prevent their occurrence. Subsequently he may pass very small calculi. Later on these rounded bodies tend to become as large as peas. In the cases where excruciating pain accompanies their transit from kidney to bladder, some signs of it are generally manifest in the urine by the presence of blood—"coffee grounds"—and a smaller quantity than normal.

That there exists a relation between gout and uric acid deposit is aptly depicted in the alternating of these two complaints, comparing one generation with another; gout, in its ordinary form of attack in the great toe,

appearing in the one, gravel in the second, and gout again in the third. This characteristic may exist in the same individual, however, for I have seen a patient who had suffered for years from gout become suddenly free from his attacks without known cause for several months, when he developed for the first time a uric acid stone in the bladder. The identity of gout and uric acid gravel I believe to be probably unquestionable; they constitute two different series of phenomena, but both arise from an overproduction of uric acid compounds coupled with an inability of the system to properly eliminate the same.

It is not my purpose to discuss here the numerous theories advanced concerning the formation and excretion of uric acid, save to say that it is generally agreed that it is formed within the tissues and is gotten rid of by the kidneys; also that experimental research seems to support Minkowski's view that it is also formed within the liver.

Now, what is the best procedure to institute with those patients who persistently pass Cayenne pepper crystals of uric acid or minute calculi? The question of avoiding or anticipating the arrival of at least the advanced condition—namely, that of calculi too large to be voided by the patient—seems to be the abstruse answer. Generally speaking, I think such patients come under observation in a tolerably early stage, although it is obvious that this is not always the case. Some are unnecessarily alarmed when the urine is only occasionally thick with urates. We must ever keep in mind the fact that sand, gravel or calculus can only be formed when the solution is maintained by undesirable circumstances in a too concentrated state. Under these circumstances the excessive acidity is of itself a natural sign of the presence of a large amount of uric acid. Although the bladder is commonly quite tolerant of a full acid condition of its contents, nevertheless the presence of a full proportion of acid has come to be regarded as sufficing to establish an almost universally adopted principle of treating the complaint (with continuous use of alkalis). If treated at home the patient is usually given bicarbonate or citrate of soda, potash or lithia; or perhaps benzoate of ammonia; or Vichy, Evian or Vals mineral waters (carbonate of soda); or some other alkaline drink is consumed in large quantities. Or, perhaps the patient is sent to drink the waters on the spot. "Carbonate of soda is the chief alkali

in the majority of natural alkaline waters" (Sir Henry Thompson), and the consequence is that if enough be imbibed the urine will clear up and become less irritating; and uric acid will no longer be deposited. But is not much more to be desired than merely to hide from view the enemy—uric acid being quite soluble in an alkaline fluid? The enemy is there, for you have not checked the acid formation. The uric acid is there, and probably in as large quantity as ever; for you have only rendered it and the urates invisible in the alkaline media. The surplus deposits have become unrecognizable by vision—nothing more. Alkalies in moderate amount cannot be said to be of absolutely no use as regards the constitutional state; but that they will not improve it to any great extent, and that when withdrawn the acid will show itself again, is the history of such cases. As to curative value, the diuretics are of no more avail. They increase the secretion of water and the solids are thus dissolved, while the perhaps already overworked kidneys are stimulated—goaded—to do still more.

Before delineating a line of treatment different from that which I have just chosen to criticize, I realize the advisability of my premising that the origin of those familiar symptoms which all agree to recognize as gout, as well as of a superabundant uric acid deposit in the urine, is due to defective assimilation on the part of organs associated with or forming the *prima via*. At the foundation of this tendency to uric acid production exists what we may understand as inactivity of the liver and skin. Insufficient work on the part of these necessarily entails unusual activity of the kidneys. Thus some of the ordinary constituents of which the solid matters of the urine are composed are augmented—not all of them, for urea is not necessarily increased; but uric acid is largely produced, and is eliminated not only in solution but in the form of crystals. When the amount of uric acid increases much above the normal and the ordinary amount of urine is present, it will not suffice to dissolve the whole, and solid uric acid is deposited in some part of the urinary channel. If this be a correct conclusion the formation of uric acid gravel is not by any means to be regarded as necessarily a kidney disease, but rather the result of an active organ vicariously relieving some other organ the function of which is torpid. The true remedy, therefore, is not to stimulate the kidneys, already overworked, by diuretics, etc., but to

look to the results attained from increasing the activity of the liver.

The most rational treatment, therefore, I believe to exist in the exhibition of such agents as will stimulate the excretory action by the *prima via* without depressing vital power. No doubt that a powerful agent for the purpose is mercury; and it is quite undisputed that relief of the symptoms above alluded to is to be obtained in a remarkable manner by the occasional use of blue pill combined with compound extract of colocynth. It is not always necessary to use mercury, however. Nature has wisely provided us with certain kinds of mineral waters, whose constituents far surpass for prolonged use either mercury or the "substitutes for mercury" (taraxacum, nitric acid, podophyllin, and the alkalies), in what is called "promoting the action of the liver." I refer to meritorious natural mineral waters—medicaments prepared deep down in the bowels of the earth by an omnipotent and inimitable pharmacist, with medicinal powers for which the physician can find no substitute, or the druggist duplicate. The mineral waters which give us best satisfaction in hepatic torpor are those marked by the common and distinctive characteristic of containing in solution sulphate of soda in considerable quantity, varying proportions of sulphate of magnesia and less important salts. The saline combinations found in natural springs have certain marked advantages over the pharmaceutically crystallized salts or those reduced by ordinary commercial processes. The advantage exists principally in the superior potency of the product from Nature's laboratory. The usual dose of sulphate of magnesia may be said to be half an ounce, but the same effect will be obtained with one-third or one-fourth of that quantity if taken in the form of mineral water. I refer to natural mineral water, for "artificial waters," however admirably prepared, are simply pharmaceutical products, and are destitute of a remarkable quality which distinguishes the remedies they are designed to imitate.

These waters are classified as the "saline purgative" and "saline aperient" groups, and should contain not less than two drachms of sodium sulphate and not less than one and a half drachms of magnesium sulphate to the pint. The best known aperient saline waters contain 150 to 154 grains of the former and 116 to 148 grains of the latter to the pint, with practically no carbonate of soda and little iron or other ingredients. Six to eight

ounces of the best of this class of waters is for the adult an average dose, and should be warmed and diluted by adding, say, a third or a half of its bulk of hot plain water. Certain of these waters are so concentrated as only to require one-third to two-thirds of the quantity above named, which has reference to the average of this class of waters; and I certainly think them preferable when accessible. If, then, a dose of either be taken in the early morning, an hour before breakfast, which should be a light meal, a full free action of the bowels will probably follow soon after. There is something which I do not pretend to explain, and certainly shall not speculate about here, which distinguishes the action of mineral waters from the action of salts which are found on our druggists' shelves. This difference is aptly depicted in the clinical manifestations; for if you evaporate a quantity of, say, Hunyadi water in a warm water-bath so as to avoid decomposition of the salt, and retain the water of crystallization, thus obtaining as perfect a product as a chemist can produce, and administer three times as much of this salt as that which exists in a dose of the natural water, you will probably not produce such efficient or certain results as the small quantity contained in the natural water insures.

Now, the principle upon which the waters of the sulphate of soda group, aperient or non-aperient, are beneficial, is that they produce activity in all the digestive functions, stimulating the excretory action of the abdominal organs, so that certain waste matters which have been hitherto thrown out as uric acid by the kidney are eliminated in some other form. It may also be said of these waters that their use can be kept up indefinitely without an increase of dose, which is certainly an important and valuable characteristic in any therapeutic agent. This system of treating a constitutional tendency to excrete uric acid in abnormal quantity, whether in the form of gravel or by the less obvious course of gouty attacks in all their varied manifestations, seems to me to have earned a right to be considered prophylactic and eminently successful, and can be more favorably pursued at home, provided certain accompanying advantages can be secured, than by sending the patient abroad. It is desirable to secure, during a course of waters at home, at least regularity of meals, scrupulous attention to diet and habits of life, and if possible to insist upon a long continued

use of the water. Moderation in diet is probably of more importance than exclusion of any particular kind of food. Milk diet, if it could be maintained a long time, would probably be the best of any exclusive diet, and should form an important part of any mixed diet. The two classes of food which it will be best to eliminate from the dietary are fatty matters and saccharine products of all kinds—the former not entirely, the latter as completely as possible. Alcoholic drinks of all kinds are, I believe, invariably pernicious in all such disorders presenting the symptoms before described as depending upon a "torpid liver," and therefore should be forbidden.

*Summary.*—The points which I wish to emphasize are as follows:

1. Calculi are of local or constitutional origin; and those depending upon a constitutional diathesis are greatly in the majority and are the ones to which I refer in particular.

2. Since uric acid forms the basis of the vast majority of calculi of constitutional origin, the question of preventing the formation of gravel resolves itself largely into one of regulating the production of uric acid and favoring its elimination from the system.

3. The true *rationale* of the unduly large formation of the urinary salts appears to be due to an inefficiency in the excreting power of the skin and liver; and the kidneys have more work than is natural thrown upon them. Uric acid is largely produced and is eliminated not only in solution but in crystalline form.

4. Alkalies and diuretics will not improve the constitutional state involved in stone formation to any great extent, and there is reason to believe that large quantities habitually taken exercise an undesirable influence, especially upon the kidneys.

5. The long-continued daily use of certain saline aperient natural mineral waters of the sulphate of soda group is beneficial in calculous disorders because they produce activity in all the digestive functions and stimulate the excretory action of the abdominal organs to the end that certain waste matters which were previously thrown out as uric acid by the kidney are eliminated in some other form.

6. Sulphate of soda is one of the most excellent therapeutic agents we possess, and deserves to be more popular than it is; but it is not as potent in the form of the commercial salt as in the form of natural mineral

water, nor can it be given continuously without increase of dose except in the form of the waters above mentioned.

419½ SANTA FE AVE.

THE CONSERVATIVE TREATMENT OF  
FIBROID TUMORS BY MYO-  
MECTOMY.\*

BY CHARLES P. NOBLE, M.D.,  
Surgeon-in-Chief, Kensington Hospital for Women, Phila-  
delphia.

The operative treatment of fibroid tumors has developed through several stages. In the beginning the removal of the tumor only was attempted. This method of operation was employed because it was considered the simplest and safest, and not from motives of conservatism. At a later date the uterus was removed together with the tumor or tumors, because it was believed to be a safer method of operation than the removal of the tumors alone. Still later the removal of the ovaries was employed to bring about the artificial menopause, and thus promote the involution of the tumor. This method was employed also upon the ground of the relative safety of the procedure.

In the development of the technique of these methods of operation the advantages of hysterectomy over the removal of the ovaries have become manifest, and this is the usual method of election. In a certain class of cases it has been demonstrated that the removal of the tumor itself (myomectomy) is a safer operation than the removal of the uterus with the tumor or tumors (hysterectomy). In the recent past true conservatism—that is, the welfare of the patient—has required the selection of one or other of these methods of operation, depending upon the nature of the case. The technical details of operation for fibroids have been so perfected, and the safety of these operations has been so greatly increased, within the past few years that it has become possible to advance conservatism a step forward, and to view the removal of fibroid tumors from a higher standpoint. Undoubtedly the ideal method of treatment of fibroid tumors is to remove the tumors while retaining the organs of generation and the functions of menstruation and procreation. This must be accomplished by broadening the field of myomec-

tomy and restricting that of hysterectomy. The object of this paper is to discuss the present status of myomectomy, and to advocate such changes in practice as will render this conservative operation applicable in many cases in which it is now necessary to resort to hysterectomy.

The first myomectomy was performed by Amussat (Memoir upon the Pathological Anatomy of Fibrous Tumors of the Uterus, etc., Paris, 1842) June 11, 1840. The tumor was a submucous fibroid in the early stages of the process of being extruded from the uterus by the contractions of that organ. Amussat performed his second operation in 1841 (*loc. cit.*, p. 41). Both tumors were removed *per vaginam*. They were not only the first myomectomies, but aside from the removal of fibroid tumors which had become polypoid and extruded into the vagina, they were the first fibroid tumors to be removed. In these operations there was no question of conservatism in the modern sense of the term. Myomectomy was performed instead of hysterectomy simply on the ground of the relative safety of the two operations; hysterectomy was yet unborn.

Washington L. Atlee was the next surgeon to perform myomectomy, and the first to systematically and continuously advocate the removal of these tumors upon scientific grounds. Atlee's first myomectomy appears to have been done for a pedunculated fibroid tumor, which was removed by celiotomy August 28, 1844, with a diagnosis of ovarian tumor. This diagnosis was corrected at the autopsy several years subsequently, when both ovaries were found *in situ* (Atlee, Ovarian Tumors, p. 249).

Atlee's first myomectomy performed *per vaginam* is recorded in his prize essay (The Surgical Treatment of Certain Fibrous Tumors, etc., *Trans. Amer. Med. Assoc.*, 1853, p. 559). The operation was begun May 8, 1845. The tumor was removed piecemeal at different times. The patient died July 16 of pneumonia. Atlee continued to operate *per vaginam* and by abdominal section, and in 1853 reported fourteen cases (*loc. cit.*). A study of Atlee's very full report of these cases is most interesting, and serves to increase one's respect for this great man, who was even more a pioneer in the surgical treatment of fibroid tumors than in ovariectomy.

It is beyond the scope of this paper to refer to numerous surgeons who advanced the operative treatment of fibroid tumors in its early stage. It must suffice to refer to a

\* Read before the Pennsylvania State Medical Society, May, 1898.

few of those who have aided in the perfection of myomectomy. Emmet working over many years perfected a method of removing intra-uterine fibroid tumors by making traction upon the tumor, and removing the tumor by cutting it up with scissors. This method was probably the basis from which developed the modern method of morcellement as applied to operations for fibroids. There is the essential difference, however, that while Emmet used the method in the performance of myomectomy, the French school have used it in the performance of hysterectomy.

A. Martin, of Berlin, in 1886 (*Diseases of Women*, American edition, 1890, p. 280), performed myomectomy for an intra-uterine tumor by the abdominal route. He states: "The great tumor was extruded from above after laparotomy and incision of the uterus. Its bed was cleansed and the uterus sutured. The union and involution of the uterus proceeded in a thoroughly satisfactory manner." This is probably the first case in which a myomectomy was done by the abdominal route for an intra-uterine tumor. Numerous pediculated tumors had been removed by abdominal section, and as early as 1853 Atlee had removed a sessile subperitoneal fibroid tumor by myomectomy (*loc. cit.*, p. 548). Martin has been a constant advocate of myomectomy for intramural fibroids upon the ground of conservatism. His advocacy of myomectomy had less weight than it otherwise would have had, because the results which he obtained were less favorable than those obtained at the same time by the adherents of hysterectomy.

No other surgeon can be specially singled out as having advanced the operation of myomectomy, but with the perfection of abdominal surgery it became possible to substitute myomectomy for hysterectomy in many cases without increasing the primary mortality of the operation, and with the great gain of conserving the organs of generation. Numerous operators, especially in this country and in Germany, embraced the opportunity to extend the field of conservative surgery. At the present time much thought is being given to the best method for broadening the indication for myomectomy. Early operation for fibroid tumors heretofore has been advocated in order to lessen the mortality of hysterectomy, the basis of its advocacy being that hysterectomy has a lower mortality than fibroid tumors when these are not removed by operation. In estimating the comparative mortality of hysterectomy

and fibroid tumors without operation, the fact must not be lost sight of that fibroid tumors are very frequently complicated by other morbid conditions, such as ovarian tumors, pyosalpinx, inflammatory disease of the uterine appendages, necrotic degeneration of the tumors, cystic degeneration, sarcoma, calcareous degeneration, and in a small percentage of cases carcinoma of the body of the uterus or of the cervix is present. The mortality of the complications alone in a given class of cases is greater than the mortality of hysterectomy, leaving aside the inherent mortality due to the tumors themselves.\*

An even stronger ground for the advocacy of early operation is the fact that myomectomy can be much more frequently substituted for hysterectomy. In my own work almost exactly twenty per cent. of the operative cases have been dealt with by myomectomy.

Certain considerations control the indication for myomectomy. The primary purpose of myomectomy is the conservation of the functions of menstruation and procreation, therefore it follows that the age of the patient and the desirability of child-bearing are the main factors in determining the indication for this operation. In women who are approaching the menopause nothing is gained by substituting myomectomy for hysterectomy. Aside from these relative indications the nature of the growth is the absolute indication for or against myomectomy. Typical cases for myomectomy are those in which but a single tumor is present, and favorable cases are those in which the number of tumors is small. When the number of tumors is great, the desirability of the operation becomes less because of the greater technical difficulties of the operation and the

---

\*In a study of my own experience in fibroid tumors (*The Development and the Present Status of Hysterectomy for Fibromyomata*, *Trans. Amer. Gynec. Soc.*, 1897), among sixty-six cases of fibroid tumor for which hysterectomy was done, the following complications were met with: Cystic degeneration, 3; calcareous degeneration, 3; sarcomatous degeneration, 3; necrosis of the tumor, 2; bilateral hydrosalpinx, 4; unilateral hydrosalpinx, 4; bilateral pyosalpinx, 4; unilateral pyosalpinx, 2; unilateral ovarian cyst, 4; bilateral dermoid ovarian cyst, 1; parovarian cyst, 1; ovarian cyst, ruptured tubal pregnancy, appendicitis, 1; intraligamentous development of the tumor, 6. I reported also three cases of cancer of the cervix complicating fibroid tumors, in which hysterectomy was not performed. Also, of seventeen fibroid tumors which had been removed *per vaginam*, five were necrotic. In my experience about seven per cent. of the fibroid tumors upon which I have operated have been necrotic.

increased risk attending it. When the uterus is studded with fibroid tumors, the operation is contraindicated, because of the impossibility of removing all of the growths and the probability that some of those remaining will continue to grow and require subsequent operation.

Myomectomy may be performed either by means of the abdominal or vaginal route. The cases best suited for the abdominal route are subserous and intramural fibroid tumors. When of large size submucous fibroid tumors also are best attacked from above. The essentials for success in myomectomy are perfect asepsis and hemostasis, in addition to a good surgical technique. Operators whose facilities do not afford these requirements should not undertake the operation. The technique of the operation is comparatively simple. The capsule of the tumor is incised and the tumor peeled out from its bed. When the capsule is large, this must be trimmed so as to facilitate the closure of the wound. The wound is then closed by continuous catgut suture, as many tiers of sutures being used as necessary to obliterate the bed of the tumor and to secure perfect hemostasis. The peritoneal covering of the uterus is closed in the usual manner. When the tendency to oozing is marked, the use of mattress sutures is of great service. The ligation of one or more of the four arterial trunks supplying the uterus is admissible when otherwise hemostasis is impracticable. The use of catgut prepared by the cumol method has given me much satisfaction.

The vaginal route is best adapted to the removal of submucous fibroids, cervical fibroids, and small subserous fibroids situated upon the anterior wall of the uterus. This latter class of fibroids is best attacked by anterior colpotomy. Through the vaginal wound the uterus is anteverted into the vagina, the tumor enucleated, and its bed sutured as in abdominal myomectomy. The vesical peritoneum is then sutured to the uterus above the wound in the uterus, and the vaginal incision closed. Cervical fibroids can be reached by splitting the cervix and enucleating them. Depending upon the location and size of the tumor, the method of operation must be varied in different cases. In some of the cases the anterior lip of the cervix may be split antero-posteriorly, in others the posterior lip. In a number of cases I have split the cervix bilaterally, enucleated the tumor, sutured its bed, and then closed the incisions in the cervix. Submucous fibroids

may be reached in two ways. The usual method, and the one which I have employed, it to split the cervix bilaterally up to and beyond the internal os. With care it is possible to avoid wounding the uterine artery and vein. This accident has never happened in my cases. Should it ever occur, the vessels would require ligation as in vaginal hysterectomy. After splitting the cervix the cavity of the uterus can be dilated with dilators, and the tumor seized with vulsellum forceps. If polypoid and of moderate size, it should be drawn down and the pedicle divided with scissors. When of larger size and not polypoid, the capsule must be incised and the tumor enucleated with the finger or some blunt instrument. Tumors of large size are best delivered by traction and morcellation, in accordance with the method advocated by Emmet. The capsule of the tumor left after its removal should be trimmed so far as possible with scissors. In my experience hemorrhage after the removal of fibroid tumors *per vaginam* has been trifling; but should it prove troublesome, it should be controlled by packing the uterus with gauze. It is conceivable that it may be sufficiently troublesome to require hysterectomy. After the removal of the tumor, the cavity of the uterus should be lightly tamponed, and the cervical incision united with catgut sutures reenforced with silkworm-gut, so that the gauze may be removed without risk of tearing open the cervix.

Anterior colpotomy followed by splitting of the anterior wall of the cervix and uterus up to and, if necessary, beyond the reflection of the vesical peritoneum has been recommended as affording ready access to submucous fibroid tumors. I have never employed the method, but theoretically it should afford ready access to intra-uterine tumors. My own experience with splitting the cervix bilaterally has been quite satisfactory, but it is quite apparent that the risk of wounding the uterine vessels is greater by this method than by anterior colpotomy. On the other hand, anterior colpotomy presents the objection that there is more likelihood of invading the peritoneal cavity by this method.

My own experience with myomectomy embraces twenty-five cases, in eight of which the operation was done by abdominal section, and in seventeen *per vaginam*. All of the patients made good recoveries. In none of the cases so far as known have fibroid nodules developed since operation. Three of the patients are known to have become pregnant

and given birth to children since their operations. One patient gave birth to twins.

The results of myomectomy in my hands have been most satisfactory. The primary mortality has been *nil*, the recovery from operation in almost all cases has been uncomplicated, and the result of the operation has been satisfactory in every case. A number of the patients were extremely ill when operated upon, due to long-continued hemorrhages and to infection or sloughing of the tumor brought about by the efforts of the uterus to expel the tumor *per vias naturales*. Three of these patients were dangerously ill from anemia and septicemia. It cannot be expected that a *nil* mortality will be obtained in a large series of cases of myomectomy, but the mortality should be lower than that of hysterectomy for fibroids. Cases suitable for myomectomy on the whole are more favorable for operation than the average cases of fibroid tumor. Cases suitable for hysterectomy include all the cases having serious complications. Cases suitable for myomectomy are seldom in desperate condition, the exceptions being those suffering from severe anemia due to long-continued hemorrhages or to infection of intra-uterine fibroid tumors.

In conclusion, I wish once more to express the opinion that the next advance in the treatment of fibroid tumors will be the general adoption of early operation and the more general substitution of myomectomy for hysterectomy as being the most conservative treatment of these growths.

#### TREATMENT OF GRIPPE.

We have already quoted the treatment given by LYON for certain of the symptoms of influenza. He also gives the following prescriptions for additional complications. For the coryza, particularly if it is marked and the discharge purulent with or without epistaxis, he employs the following:

- ℞ Vaseline, 2 ounces;  
Boric acid, 2 drachms;  
Menthol, 7 grains.

A little of this is placed in the nostril by the finger five or six times a day, or the following powder may be used:

- ℞ Boric acid, 2 drachms;  
Menthol, 2 grains;  
Hydrochlorate of cocaine, 1 grain.

A small pinch of this is snuffed up the nostril a few times a day. If irrigation of

the nasal cavity by means of hot boric acid water is needed, it should be done with care lest infection of the Eustachian tube take place. For the sore throat and laryngitis he recommends hot water compresses to the throat. Inhalations of steam laden with the following drugs, which are placed in the hot water, are useful:

- ℞ Alcohol (70-per-cent.), 1 ounce;  
Menthol, 15 grains.

A teaspoonful of this is to be added to a pint of hot water, and at the same time another teaspoonful of benzoin may be poured in and the steam inhaled. Sometimes gargling with very hot water, to which has been added boric acid, is useful, or two teaspoonfuls of the following mixture may be placed in hot water and used as a gargle:

- ℞ Bromide of potassium, 1 drachm;  
Hydrochlorate of morphine, 2 grains;  
Antipyrin, 30 grains;  
Hydrochlorate of cocaine, 2 grains;  
Distilled water, 2 ounces.

In the early stages of the bronchitis without expectoration, but with cough, cherry-laurel water, paregoric, tincture of hyoscyamus, aconite or benzoate of sodium are useful. The following may be prescribed:

- ℞ Fluid extract of hyoscyamus, 1 drachm;  
Cherry-laurel water, 3 drachms;  
Syrup of tolu,  
Syrup of orange flowers, of each 6 drachms;  
Syrup, 4 ounces.

A dessertspoonful every two hours.

Or,

- ℞ Dover's powder, 30 grains;  
Powdered squill, 20 grains;  
Quinine sulphate, 30 grains.

Make into 20 cachets and take three to five a day.

Or the following may be employed:

- ℞ Hydrochlorate of morphine, 1 grain;  
Hydrochlorate of cocaine, 2 grains;  
Antipyrin, 30 grains;  
Water, 4 ounces.

Three or four teaspoonfuls a day in a little hot whiskey or rum.

For bronchitis with abundant expectoration:

- ℞ Terpene hydrate, 4 grains;  
Glycerin and syrup, a sufficient quantity to make one pill.

Three to five a day.

Or,

- ℞ Terpene and benzoic acid, of each 2 grains;  
Dover's powder, 1 grain.

Make into one pill and take six a day.

### THE NORMAL GASTRIC MOVEMENTS.

Notwithstanding the very numerous studies which have been made during the past ten years upon the processes of gastric digestion and upon the movements of the stomach, there yet remain large open spaces in our knowledge of the two physiological processes which we have named. The fact that the stomach is an internal organ which cannot readily be observed in its physiological activity has forced us to rely upon results obtained by the use of the gastric tube, or by the passage of esophageal and gastric bougies which have given us indefinite information; and yet as a matter of fact, physiologists have from the earliest times been interested in the two questions of gastric digestion and gastric movements. With the employment of the Roentgen rays in medicine new possibilities for the study of the action of internal organs have presented themselves, and some of the most useful results so far obtained in clinical medicine and physiology, from the use of these rays, are to be found in a paper con-

tributed by Dr. W. B. Cannon in the *American Journal of Physiology* for May, 1898.

His experiments consisted in administering to cats food which had been mixed with subnitrate of bismuth, which latter substance is impervious to the Roentgen rays, and, by giving a sufficient quantity of food to practically fill the stomach, changes in the contour of this viscus were of course represented with the changes in the shape of the bismuth-laden food mass. A large number of animals were observed over a considerable period of time, and Cannon finds that the stomach consists, physiologically, of two distinct parts, the pyloric part and the fundus; and that over the pyloric portion when food is present, constriction waves continually course towards the pylorus. On the other hand, the fundus is an active reservoir for the food, and when salivary digestion is advanced this reservoir squeezes its contents out into the pyloric area. For a thorough understanding of his paper it is necessary for us to remember that he makes the following divisions of the stomach, namely, the cardiac portion, which extends from the left edge of the stomach half across its length, and the pyloric portion, which extends from this point to the beginning of the small intestine. This pyloric portion is, however, divided into two parts—the antrum, which is just at the beginning of the small intestine, and the preantral portion, which extends from the middle of the stomach nearly to the pyloric opening.

Cannon finds that the stomach is emptied of food by the formation, between the fundus and the antrum, of a tube along which constriction waves pass; that the food in the fundus is pressed into this tube and the tube and antrum slowly cleared of food by means of constriction waves. In other words, the pyloric half of the stomach, called the preantral portion, forms itself into a tube which conveys food from the fundus to the pyloric orifice. But the process of propulsion is not all from the fundus towards the pylorus. On the contrary, the food having passed through the tube in the preantral portion is once more pressed upon in such a way that the food returns backward along the path which it has followed and thus becomes thoroughly mixed with gastric juice, so that while its progress is ultimately towards the pylorus, this progress is for a time oscillating in character.

Again, he finds that the pylorus does not open at the approach of every wave bearing food, but only at irregular intervals, and, still

more interesting, that the arrival of a hard morsel causes the sphincter to open less frequently than normal and thereby the passage of the already liquefied food is delayed, for the solid food remains in the antrum to be rubbed by the constrictions until triturated into small particles, which are softened by the gastric juice. If, however, the morsel is too hard to be softened and digested in the stomach, it ultimately escapes into the intestine. Of still greater interest in connection with these studies are the observations which Cannon has made concerning the function of the fundus of the stomach. He finds that food in this portion of the viscus is not moved by peristalsis and is not mixed with gastric juice, but that the fundus forms a sort of pouch in which salivary digestion of the starches and general softening and maceration of the food can be carried on for a considerable period of time without being stopped by the acid gastric juice. This result is of interest, as it explains the clinical fact that both taka-diastase and pancreatin are known to carry on their digestive function in the stomach for a considerable period of time after food is taken, although theoretically the acid gastric juice should inhibit the activity of the pancreatin, at least. It also explains an interesting fact which the writer of this editorial has noticed in a number of cases, namely, that the stomach seems to possess the ability of retaining certain articles and of passing others into the small intestine. Thus if a purgative is taken after food has been swallowed and a copious movement of the bowels is produced within a few hours—as it is, for example, after the use of a saline purgative—none of the undigested food, at least in the normal individual, escapes from the bowel, whereas mucus and other materials are frequently washed out. In other words, it has seemed to the writer that the alimentary canal possesses a selective ability whereby it retains substances with which it has not finished its physiologic function and passes on those which do not need to be retained in the stomach.

We are wont to hear a great deal at this time of nervous dyspepsia, and undoubtedly nervous dyspepsia arises from the fact that so much nervous energy is expended in the ordinary pursuits of life that a sufficient amount is not reserved for the processes of digestion, and as a result digestion is impaired or entirely prevented. Cannon's studies indicate the fact that marked nervous excitement also inhibits the movements

of the stomach. Thus Cannon found, when the cats upon which he experimented became irritable or showed any signs of distress, the digestive movements of the stomach were at once stopped, but as soon as the animals were soothed or their anger appeased, the digestive movements already described at once reasserted themselves.

It is studies such as these of Dr. Cannon which attract the practising physician to the study of physiology, a department of medicine in which many practising physicians are woefully ignorant because they do not understand the direct bearing of physiological knowledge upon the practise of medicine. Much of the so-called physiology taught in the medical schools is theoretical or so deep as to seem to have little bearing upon bedside experience, and we welcome these studies which, while scientific and accurate in the realm of physiological science, are also productive of increased knowledge which may prove of value to the sick.

#### *THE VALUE OF METHYLENE BLUE IN THE TREATMENT OF ACUTE GONORRHEA.*

---

A few years ago a substance known as pyoktanin was widely employed, in the treatment of the various septic conditions, as a mild germicide. It was also used as an antiseptic in various ailments and found favor in the eyes of many practitioners. A great difficulty with its general use was the deep staining of everything with which it came in contact, and this doubtless, more than any other reason, has prevented pyoktanin and similar drugs nearly related to it from being employed as widely as would otherwise be desirable. At the present time it would seem that methylene blue finds its chief usefulness in the treatment of malaria, when quinine cannot be taken, in the cure of severe neuralgia, and in the treatment of acute gonorrheal urethritis. Our attention has been called to the latter use of it by a paper recently published by Dr. Orville Horwitz, of Philadelphia, who has employed methylene blue in 105 cases of this disease with very satisfactory results, not only clinically, but also bacteriologically, in that examinations of the secretions and pus from the urethra show that the methylene blue exercises a distinct influence upon the gonococcus.

The dose of methylene blue which he used was two grains two or three times a day, but it is to be noted that about one-fourth of the

cases taking this suffered from slight diarrhea and stranguy, under which circumstances the dose was decreased about one-half, and never did one-grain doses produce unpleasant result. Naturally the two-grain doses were more efficient when they were well borne by the patient. In all instances the urine became a deep blue hue owing to the drug being eliminated by the kidneys. Dr. Horwitz states that in four or five days the pronounced purulent discharge was changed to a slight mucoid excretion with a modification in all the inflammatory symptoms. The best method of administering methylene blue in Dr. Horwitz's opinion is in the following formula:

- R. Methylene blue, 2 grains;  
Oil of sandalwood, 3 grains;  
Oleoresin of copaiba, 3 grains;  
Oil of cinnamon, 1 drop.

Mix. Dispense in capsule. One dose.

In addition to this capsule internally permanganate of potassium solution was employed for irrigation purposes, beginning with a strength of 1:2000 and gradually increased until the preparation reached 1:1000. Dr. Horwitz concludes his paper by the following summary, which expresses his opinion as to the value of this method of treatment:

1. That methylene blue is a germicide of great value in cases of acute urethritis, due to the presence of gonococci.
2. That it will not abort the disease, but will materially shorten its duration.
3. That it markedly lessens the tendency to complications.
4. That it is not to be employed in the treatment of acute urethritis, unless a bacteriologic examination demonstrates the existence of gonococci.
5. That the remedy should be employed as soon after the infection as possible.
6. That the proper dose with which to begin treatment is one grain three times daily, to be increased to two grains if the remedy is well borne.
7. That the beneficial action of methylene blue is enhanced and the duration of the disease is shortened by combining it with copaiba, sandalwood, and salol.
8. That the injections of potassium permanganate by means of a hard syringe, or if possible by irrigation, administered in the early stages of the disease, and followed during the period of decline by an astringent injection, have a marked tendency to lessen the duration of the malady.
9. That methylene blue always has the effect of turning the urine to a deep blue

color. Of this fact the patient should always be informed to prevent unnecessary alarm.

10. That methylene blue is of no service in cases of non-specific urethritis.

#### THE VALUE OF JAMBUL IN DIABETES MELLITUS.

The fact that diabetes mellitus is in some cases a hopeless disease against which both physician and patient struggle without effect causes us to be continually on the lookout for some remedy which can be considered a specific, it being forgotten in many instances that in all probability diabetes is but a manifestation of a series of lesions rather than of a single pathological condition. Recently in the January issue of the *Indian Medical Gazette* Dr. Macphail speaks in a laudatory way of the influence of jambul in the treatment of this malady, although he admits that the patients return to say that while it temporarily relieved them, in many instances the symptoms recurred. In the same journal for March, 1898, Mitra, of Kashmir, in writing about Dr. Macphail's contribution, points out that this drug was first recommended by Banat Walla, whose experiences were recorded, and by Quantjer, of Batavia, and that in the *Practitioner* for January, 1891, Kingsbury and Mahomed published favorable results in isolated instances from its use; so, too, Lewischen in the *Berliner Klinische Wochenschrift* of February 23, 1891, and Dujardin-Beaumetz in the *Bulletin de Thérapeutique* for March, 1891, considered that this remedy in combination with a strict diet was useful in mild cases but useless in severe ones, which is practically equivalent to saying that it is of no value at all, for every one knows that in mild cases dietetics should be given nearly all the credit for any improvement.

Mitra tells us that a careful analysis of a large number of cases in India in which this drug has been tried under the most favorable conditions, the seeds being fresh, shows that it has no claim to be considered a cure for diabetes. He thinks that given a case of ordinary diabetes it may be well to try the fresh seeds with a strict dietary for a short time, and then if no value results we should cease its use at once.

These conclusions reached by Mitra are in accord with our own. In the few instances in which we have given this drug it has failed to produce any material influence.

## Reports on Therapeutic Progress

### *THE USE OF HYDROCYANIC ACID AS AN ANTIDOTE TO CHLOROFORM.*

FREDERICK HOBDAY, a veterinarian, writes a paper on this topic in *The Lancet* of January 1, 1898. He points out that the extreme frequency with which records of death from the anesthetic administration of chloroform appear in the professional journals must make welcome the addition of another antidotal agent to the list of those with which we are already acquainted. The idea of using hydrocyanic acid as an antidote to chloroform first suggested itself to the writer about two years ago when watching the different effects of the two drugs upon the respiratory tract when used to produce death, and particularly from having observed the powerful and rapid excitant result which follows absorption of a toxic dose of the acid. In 1896 there was published in detail a list of some forty-three observations upon various animals, including dogs, cats, a horse, sheep, and calf, showing the results obtained by this method of resuscitation and also a few cases illustrating the palliative and sedative effects produced on the respiratory efforts by chloroform inhalations upon animals suffering from overdoses of hydrocyanic acid. Since then the writer has been able to collect fifteen additional consecutive cases in which it has been successfully used in the college canine clinique after respiration had actually ceased, and he has also had confirmatory reports of its antidotal value from veterinary practitioners in various parts of the country. The results have certainly been in the highest degree satisfactory, so much so that when chloroforming animals the only antidotes they now have at hand ready for use are those of hydrocyanic acid and liquor ammoniæ fortior. As soon as breathing ceases or becomes dangerous artificial respiration is resorted to, the tongue being continuously pulled well forward in a jerky manner and a full medicinal dose of Scheele's acid placed as rapidly as possible at the back of the throat. When respiration has recommenced the ammonia vapor is applied cautiously to the nostrils, and in the majority of cases a safe termination ensues.

The method of artificial respiration preferred is that of laying the animal in a horizontal position on its right side and pressing the ribs in a short, sharp, jerky manner; they have tried everting the body, but the writer

is convinced that this is a bad method in the dog and cat, as the intestinal organs press upon the diaphragm and limit the capacity of the thorax. They have also tried placing the body in the opposite position with the idea of removing all pressure of the abdominal organs from the thorax and its contents, listening carefully at the same time in each case to the heart sounds with the phonendoscope; but he is firmly convinced that the heart sounds are stronger and less labored when the body is placed horizontally.

When reasoned out theoretically, in addition to the results of practical work, hydrocyanic acid stands foremost amongst agents likely to prove of antidotal value; for what more rapid or powerful respiratory stimulant have we? Its use is attended with no more danger than that of strychnine—in fact, in the dog and cat with far less. Its rapidity of action is unquestionable, it is easily absorbed from any of the entrances of the body, and it has the advantage over ammonia that it does not irritate the tissues to which it is directly applied. Besides these things, not only has it an immediate effect in starting the respiratory mechanism, but when once this has commenced the stimulating effect of the acid is maintained for twenty minutes or half an hour and keeps going until the breathing is able to resume its normal aspect and the patient is out of danger. The writer is aware that many cases will recover by the aid of artificial respiration alone, but he is perfectly convinced from tests applied to this point, and from an extensive experience of the results which were obtained with other antidotes before hydrocyanic acid was tried, that the use of the acid gives an enormously higher proportion of successes. When compared with hypodermic injections of strychnine, ether, or saline solution, or the use of amyl nitrite or ammonia vapor, its effect is visibly much more rapid and powerful. Scheele's acid is of course more rapid and powerful than the British Pharmacopœia acid and acts best when given undiluted.

With reference to the method of administration the best way to apply it is undoubtedly by means of a graduated drop-tube on the back of the tongue. Hypodermic injection does not seem to give such good and rapid results, and the direct forcing of the vapor up the nostril by means of bellows is decidedly dangerous from the risk of administering an overdose. Full medicinal doses are necessary, as when an animal is under chloroform the effect of the acid is not visible

quite so quickly as when no chloroform has been used. If an overdose be given the judicious use of the anesthetic vapor will combat and quiet the spasm of the respiratory muscles until the excess of acid has had time to become eliminated from the system. In several cases the writer has had opportunities to test this before experience taught the exact dose. This latter averages in the dog and cat about one minim of Scheele's acid for every seven or eight pounds of live body weight. The object must be to give just enough acid to produce the preliminary excitant effect upon the respiratory center, and of course, like all antidotes, the sooner it is administered after dangerous symptoms have appeared the more likely is the result to be favorable.

#### THE USE OF VENESECTION.

*La Presse Médicale* of February 2, 1898, tells us that HERVIEU has reported to the Académie de Médecine of Paris that he has employed blisters or scarification to the abdominal wall with great success in the treatment of puerperal peritonitis. He has never seen the use of blisters produce nephritis or urinary symptoms.

[We doubt whether this treatment will be serviceable.—Ed.]

#### THE TREATMENT OF CARDIAC COMPLI- CATIONS IN PREGNANCY.

In *La Presse Médicale* of February 2, 1898, VACQUEZ and MILLET give the following directions:

For the prevention of accidents from cardiac disease in gravid women two indications are necessarily carried: First, rest in bed; second, an absolute milk diet. These prescriptions should be adhered to for the period of five or six months; only a sufficient quantity of exercise being taken each day to maintain the health, and the heart being given a rest during the remainder of the twenty-four hours. Should there be any evidences of scanty urinary secretion theobromine may be given as a diuretic, and it may be necessary to give saline purgatives to relieve the bowels or the kidneys. These may be given every three or four days. Should the symptoms of cardiac disease manifest themselves in asystole, anasarca, hepatic and renal congestion, then digitalis in fractional doses employed as an infusion may be resorted to with advantage. At the same time it may be

necessary to use venesection or active saline purgatives. Should there be pulmonary congestion, as a result of cardiac lesion, venesection, hot applications to the chest or wet cups may be needed. Theobromine should be given to stimulate the kidneys, and fractional doses of Dover's powder may be used with excellent results. Should the symptoms become very grave we may induce labor, using chloroform in small quantities and supporting the heart by preparations of digitalis. Although chloroform is supposed to be a cardiac depressant its use probably puts aside more danger than it itself causes, particularly if the heart is protected by doses of digitalis. So far as the prophylaxis of cardiac disturbances in pregnancy are concerned the authors quote Peter as having forbidden women with cardiac affections to marry. He, however, makes this rule: Permit marriage if the cardiac lesion is simple and there is no asystole. Oppose marriage if the cardiac lesion is complicated or associated with asystole, or if evidences of mitral regurgitation are marked.

#### THE LOCAL TREATMENT OF ACUTE AR- TICULAR RHEUMATISM.

*La Presse Médicale* of February 5, 1898, gives the following treatment for this condition: The local use of an ointment composed of liquid vaselin one ounce, salicylate of methyl half an ounce; this is smeared upon lint and bound about the joint, and the lint is now in turn covered with gutta-percha. In other cases an ointment composed of salicylic acid, as follows, may be used:

- ℞ Vaseline, 1 ounce;  
Salicylic acid, 45 grains.

In still other instances salicylic acid can be gotten into the system through the skin by the following means:

- ℞ Salicylic acid, 1 drachm;  
Salicylate of sodium, 60 grains;  
Extract of belladonna, 15 grains;  
Vaseline, 1 ounce.

This is applied in the same way as the ointment of the salicylate of methyl.

Salol is said to be especially useful in gonorrheal rheumatism. It may be dissolved in ether and used in the following prescription:

- ℞ Salol, 1 drachm;  
Menthol, 30 grains;  
Ether, 1 drachm;  
Lanolin, 1 ounce.

Guaiaicol when locally applied is also a powerful pain reliever as well as an antipy-

retic. It may be painted upon the part in the following solution:

- ℞ Pure guaiacol, 1 drachm;  
Alcohol (85-per-cent.), 1 ounce.

One-fourth of this mixture is sufficient for one application. Too frequent application of it will cause too great a decrease in temperature. After it is applied the part should be covered by an air-tight bandage. The following ointment may be used in its place:

- ℞ Guaiacol, 1 drachm;  
Vaseline, 1 drachm.

Or the following used:

- ℞ Guaiacol, 1 drachm;  
Salicylic acid, 30 grains;  
Salicylate of methyl, 1 drachm;  
Vaseline, 1 ounce.

This mixture is very active, but possesses an intensely strong odor.

Sometimes good results follow the application of the following prescription:

- ℞ Guaiacol, 1 drachm;  
Terpinol, 3 drachms;  
Alcohol (85-per-cent.), 4 drachms.

#### ON THE TREATMENT OF MALARIAL FEVERS.

M. C. NANJUNDA ROW, of India, writes on this subject to the *New York Medical Journal* of January 15, 1898. He advances a method of treating malarial fevers. According to this method, the dose of quinine required is not a large one; and the writer has had no occasion to give more than a gramme (fifteen grains) of quinine sulphate in one dose in even some of the refractory cases that he has had to deal with in those parts, and he has not met with a single case in which any ill effects of quinine were manifested—not even vomiting, which so frequently follows the administration of large doses of quinine.

The method is one advocated strongly by the late Dr. George Smith, once the senior physician of the General Hospital, Madras, and it depends on the fact that the best time for administering quinine is when the pathogenic germs are in the most weakened condition, and not when they are in a vigorous condition. Dr. George Smith, with a view to impress on his students the importance and reasonableness of his method of treatment, used to teach them graphically that the best treatment for malarial fevers was to "strike the enemy (malarial germs) when he is weakest, with the strongest weapon (a fairly large dose of quinine)," and that in

all cases of malarial intermittent fevers the actual attack of rigors and fever was the result of the war that was taking place in the system between the malarial germs and the phagocytes, and the cessation of fever was an indication of the defeat of the enemy, caused partly by their destruction and partly by their being weakened. The interval indicates the rest and the time required for the growth of the younger germs and for the recovering of the lost strength by the weakened ones for a further attack, so that the enemy is in his weakest condition as soon as the fever begins to subside; and it is then that a large dose of quinine, the specific *par excellence* for malarial disease, is to be administered and its effect prolonged by frequent smaller doses at intervals of from four to six hours for some days after that. Whatever the explanation may be, such of us as have followed his directions have yet to find a case which has not yielded to this method of treatment.

The actual method employed by the writer in all cases of intermittent fevers is never to give quinine either before or during an attack. He always waits for the attack to subside before giving any medicine; and during the attack he allows the patient to have any hot drinks he may like, such as coffee, tea or warm milk, or iced water or milk if preferred. The writer never gives any antipyretics to bring down the fever, as he has always found that the reduction of fever by means of an antipyretic prevented somehow the full action of quinine, and recurrence of the attacks has been common only in such cases. But when the fever begins to subside in the usual course, and the patient begins to perspire freely and to feel free from headache and other uncomfortable symptoms, the writer gives him from ten to fifteen grains of sulphate of quinine for the first dose, and then five grains every four, five, or six hours after that (in many cases not more than four times a day) for a week at least, after which time he continues quinine in two-grain doses with four or five minims of Fowler's solution (liquor arsenicalis, B. P.) twice a day, after meals, for a fortnight longer.

If quinine is administered in this way it is very rarely that another attack occurs. In the writer's experience of many cases of malarial intermittent fevers of all types, he has not had more than five or six cases in which the attack recurred more than once, and those rapidly yielded to the quinine

similarly administered again. Larger doses than fifteen grains, as advised by Dr. Ballagi and others, are perfectly unnecessary and are chiefly instrumental in producing many of the ill effects of quinine poisoning, so to speak. As a general rule Row prescribes only ten grains of sulphate of quinine for an adult for the first dose, and it is only in rare instances that he gives fifteen grains, and he has had no occasion to use any larger dose than this, as by the use of this method the very next attack is invariably prevented.

The form in which he gives quinine is that of soft gelatin capsules containing measured quantities, or that of freshly made pills with glyceride of tragacanth, or that of wafers. It is only rarely he orders it as a mixture or solution, more especially in cases of children and others who cannot swallow a pill, however soft and small it may be. Though the solution of quinine does undoubtedly act much sooner and much more efficiently, it has two important drawbacks, viz., its bitter taste and its producing vomiting oftener than the capsules, wafers, or pills, freshly prepared. Certainly, as Dr. Ballagi says, compressed tablets and hard-coated pills are to be condemned, for he knows of a case in which a brother practitioner prescribed seven of these hard-coated pills of two grains each, and six of them were passed out in the patient's motions two days after, intact.

#### COLITIS.

In the *Birmingham Medical Review* for January, 1898, ARTHUR FOXWELL, in writing of colitis, has the following ideas to convey as to treatment. He says when you feel any certainty that you are dealing with a specific poison, then no doubt a specific remedy should be employed and chiefly depended upon. In acute dysentery, ipecacuanha has a specific value, and according to Kanthack and Caddy, the de-emetinized drug gives as good results as that retaining the emetin, whilst the painful depression and nausea of emetin is avoided. But even with amebic dysentery, ipecacuanha is by no means universally used. The French surgeons use it apparently chiefly for its emetic qualities and not as a specific. Bretonneau advised large doses of salines, whilst Leahy, of Hyderabad, saturates seven fluidounces of water with sulphate of magnesia, to the solution adds one ounce of dilute sulphuric acid, and gives half an ounce of the mixture every one or two hours. He says he thus treated ninety-five

consecutive cases with only three deaths, and two of these three were brought to him moribund.

If there be no evidence of specific infection, then a good plan is the following: Administer a powder of morphine  $\frac{1}{4}$  grain, hydrargyri subchloridi  $\frac{1}{4}$  grain, every two hours by the mouth. By the bowel give every hour a two-pint simple enema, containing two ounces of boracic acid; this will soon be returned, and after its return give a pint enema of starch containing ten drops of laudanum. As nourishment, small quantities of brandy mixture every hour, with plenty of bland liquid and frequent ounce doses of well cooked sago, arrowroot, or custard. If there be much pyrexia or any localized abdominal tenderness, then ten to thirty leeches over the tender spots will be efficacious in relieving pain, pyrexia, and diarrhea. Constant hot fomentations to the abdomen no doubt ease the pain. As far as possible there should be complete rest in bed. In the chronic stage liquid, bland, unstimulating food should alone be taken; skim milk acts excellently. Calomel, rhubarb, or other hepatic stimulant should be taken frequently in small doses, for there is a great tendency to congestion of the liver, probably from toxic absorption. The bowels should be kept open daily; for this purpose a drug which increases peristalsis is the most useful. The writer has obtained the best results with cascara and belladonna. Even in the chronic non-amebic varieties he has found moderate doses of de-emetinized ipecacuanha of considerable service, given thrice daily for a week at a time. But persistent antiseptic enemata with occasional injections of nitrate of silver, sixty grains to the pint, is the treatment which seems most rational, and that which has proved most successful.

Massage of the abdomen, though it has soothed pain, has not in the author's hands had much curative effect. Both it and enemata are liable to produce perforation if roughly administered. Lying out-of-doors on a couch for most of the day is perhaps the most excellent of all methods of cure, and if the patient be warmly clothed with flannel, it is quite without danger.

But whatever be done, colitis is a very stubborn disease, just as is its congener appendicitis. Both are sadly given to relapse, and with each relapse we are confronted with the danger of perforation. Unfortunately, as we now think, we cannot remove the colon as we can the appendix. However, this may

not be an unmixed evil, for the after-history of the amputated appendix has yet to be written.

The writer is not at all sure whether it would not be wisest, as soon as a case has become chronic, to do a right colotomy both for the purpose of relieving the colon of fecal irritation and, more important, to enable astringents and antiseptics to be thoroughly applied to it. This treatment has already been suggested and successfully carried out by Mr. Mayo Robson. The writer doubts if it is ever of much value to do it for late obstruction or peritonitis; the gut is then too deeply and extensively diseased for any curative treatment; the result, at the best, can only be the annihilation of the large intestine and the formation of an artificial anus in the right inguinal region; but even this is little more than a pious aspiration, for five feet of deeply ulcerated and often sloughing intestine is not likely to lie encircling the belly in placid effacement.

Performed at an early stage and well followed up with persistent cleansing and stimulation, this method of treatment holds out great prospect of cure. For this early performance we want absolute certainty of diagnosis, which is often most difficult or impossible to attain; further, we require to know the degree of the lesions already inflicted—a still more arduous task. Unless we know these two things we cannot with any confidence reassure the patient as to the temporary character of the artificial anus, and if we are unable to do this we can scarcely wonder at his refusing to suffer so grave and disgusting a mutilation.

#### TINCTURE OF MYRRH IN DIPHTHERIA.

Dr. STRÖLL, writing in the *Allgemeine Medicinische Central-Zeitung*, very strongly recommends tincture of myrrh in diphtheria. The mixture he uses is composed of tincture of myrrh 4 parts, glycerin 8 parts, and distilled water to 200 parts. This is given very frequently—every hour or even every half hour in the daytime and every two hours at night, infants up to the age of two taking a large teaspoonful (seventy-five minims), older children double that quantity, and adults three times as much. This is continued until the membrane has nearly disappeared, when the doses are only given every two hours. After all the membrane has gone the treatment is continued for a couple of days, the interval

between the doses being increased to three hours. This, of course, is with the view of preventing any recurrence. Usually the fever and lassitude disappear in twenty-four hours, so that a child may frequently be found within that time sitting up in bed playing. He says that there does not seem to be any need for local treatment, but in the case of older children and adults a gargle containing one-half per cent. resorcin may be employed every hour or oftener in the daytime, and where it is desired the tonsils may be painted every hour with the tincture of myrrh undiluted. Where the larynx is involved Dr. Ströll prescribes the myrrh and glycerin mixture in an inhaler or spray to be used every half hour. By the employment of this method Dr. Ströll states that he has only lost one case out of eighty, and he has collected reports from several other practitioners in various parts of the world who have treated altogether 182 cases with 22 deaths. No mention, however, is made in his own or in the other cases of bacteriological verification of the diagnoses. The *rationale* of the efficacy of myrrh is supposed to be that this drug increases the phagocytic elements in the tonsils.—*The Lancet*, Jan. 1, 1898.

#### ESSENCE OF NATURAL WINTERGREEN AND ESSENCE OF ARTIFICIAL WINTERGREEN IN THE TREATMENT OF RHEUMATISM.

VIDA writes that he has substituted since the month of July, 1896, the application of compresses soaked in essence of wintergreen for the ingestion of salicylate of sodium in rheumatic patients whose digestive tubes and nervous systems it was important to consider. He noted at the onset in a certain number of patients some cutaneous manifestations varying from simple temporary erythema to the reappearing papulous eczema. In all the rheumatic patients the essence of wintergreen was applied according to the process become classic of 50 to 100 drops poured upon a double fold of aseptic gauze and covered by an impermeable material applied for some hours either to the forearm or to the leg, and renewed twice every twenty-four hours. Surprised at these cutaneous accidents which manifested themselves, especially in a series, and which could not be imputed to an exaggerated susceptibility of the integuments of these patients, the writer sought for their cause and arrived at the following conclusions:

There exist now in commerce two essences of wintergreen indifferently utilized in the drug business, and differentiated only by their price, varying from the single to the double. The one, the natural essence of wintergreen, is of a reddish-yellow color, having an oily odor, essentially extracted by distillation from the *gaultheria procumbens* or *palommier*, and is a mixture of hydrocarbons not yet perfectly defined and of methylic salicylate in the proportion of nine-tenths. The other, the artificial essence of wintergreen, is colorless, with an acrid odor, empyreumatic, recalling the odor of coal smoke, is pure methylic salicylate, and is obtained synthetically. On simultaneously applying to the two forearms of a rheumatic patient according to the method already described some compresses, the one soaked with the natural essence and the other with the artificial essence, it may be easily noticed that no reaction is produced upon the section of the member in contact with the pure methylic salicylate. The part treated with natural essence of wintergreen is, on the contrary, more or less red, painful, and covered sometimes with rubeoliform eruption. Methylic salicylate cannot have a different action according to the product employed. It is, then, necessary to conclude that the irritating action of natural essence of wintergreen is due to resins of an undetermined nature (*gaultheriline*, etc.) mixed with the salicylate. It is important, in order to avoid all irritating action appearing to counterbalance the excellent effects of this cutaneous medication, to renounce the vague appellation of "wintergreen," which leaves to the preparer the choice of employing the natural or artificial essence, and often of mixing the two essences delivered by the producer, and to prescribe the pure methylic salicylate deprived of all irritating action and not leaving any doubt as to the product to be employed.—*The Lancet*, Jan. 1, 1898.

---

**THE PRINCIPLES WHICH GOVERN TREATMENT IN DISEASES AND DISORDERS OF THE HEART.**

The *British Medical Journal* for April 2, 1898, contains a lecture on this subject in which DOUGLAS POWELL tells us that the most common mistake that one observes in the use of digitalis is that too large a dose is prescribed at first, which tends to premature arterial contraction and cumulative effects. Then, with the appearance of these physio-

logical symptoms the drug is stopped, and some other medicine substituted, until the pulse again calls for its administration. In this haphazard way of using digitalis the heart is never held in good control. In exceptional cases, where there is urgent need to push the drug, digitalin is best used subcutaneously. In ordinary cases a dose of ten minims of the tincture every four, or fifteen minims every eight, hours, or five minims every waking hour, is sufficient. Thus given, the patient being at rest, it generally takes about three days before the pulse is under control, and the urine begins to increase. When its decided effects are thus gradually developed the drug should be steadily continued in doses calculated to maintain its effect. With ordinary watchfulness there is no risk whatever; timely warning of excess is given by the pulse, which having become slow begins to exhibit small intermediate beats, and especially a tendency to go in couples. This is always a sign to reduce the doses or to omit for a few hours. The sickness that occasionally—too often—supervenes with digitalis is most troublesome. An occasional mercurial will sometimes prevent it, a change to digitalin in equivalent doses may be tried, or a tumbler of very hot water taken occasionally. In some cases it is not to be overcome except by omitting the drug; the patient is usually well under the influence of the drug before this symptom appears, in which case a small dose of digitalin by the mouth or hypodermically may be sufficient to maintain its effect on the heart.

In speaking of digitalis, Powell has regarded that drug as representing the whole therapeutic group. Digitalis is so far in front of all the others in efficacy that in critical cases he never thinks of prescribing any other member of the group before it. *Strophanthus* comes next to it in usefulness, and in physiological experiment is even more powerful. Clinically, one is not so well satisfied with it, and this may possibly be prejudiced, but he has had doubts about its stability in prescriptions. It causes the same troublesome nausea. The one reason for its use is that it affects the small vessels less and this gives it an advantage in some cases, particularly perhaps in carrying on the effects of digitalis in convalescent aortic regurgitant and mitral stenosis cases. But as he has endeavored to point out, under most conditions calling for its use this very action upon the arterioles is one of the valuable attributes of digitalis, and explains, possibly, its superiority over *strophanthus*.

thus. He frequently, however, combines the two drugs when he wants to secure an increased cardiac effect without using digitalis in doses large enough to contract the vessels too much. Convallaria comes next for mild cases, and he has occasionally used sparteine. One may observe that the earliest sign of amendment in cardiac failure is an increased flow of urine. A somewhat analogous relief of the stress of symptoms will often be observed with the commencement of dropsical cellular and peritoneum tissues. The peculiar restlessness and discomfort that precede the onset of dropsy are sometimes very remarkable, and the dropsical effusion should rightly be regarded as one of those compromises of Nature which enable the vital machinery to go on a little longer. Dropsy is due primarily to a leakage from the congested capillaries into the cellular tissue. It is also due to a retarded removal of the fluids by the lymphatic vessels.

*PHYSIOLOGICAL EXPERIMENTS WITH  
INTESTINAL IRRIGATION ON PULSE  
TENSION, TEMPERATURE, RENAL  
SECRETION, AND INTESTI-  
NAL ABSORPTION.*

The *New York Medical Journal* of January 29, 1898, contains an article by KEMP on this topic. He finds that hot irrigation, 110° to 120° F., when prolonged, increases the temperature of the body and blood. The increase of blood temperature is possibly due in part to the contiguity of the solution to the great vessels, as there does not seem to be a proportionate ratio of increase of the temperature of the body to that of the blood if due merely to effect on heat centers. In other words, the influence on the blood temperature seems to be greater in proportion than it does on that of the body. The heated blood would undoubtedly be of value in stimulating the heart, and this shows the further advantage of irrigation at a high temperature in shock and allied conditions.

If the patient's temperature is already high, it might be dangerous to irrigate with fluid at a high temperature for fear of increasing the temperature of the patient.

Cold irrigation reduces temperature, and is depressing after twenty to twenty-five minutes. At first, cold acts as a stimulant.

Clinically, irrigation at a high temperature has proved to be excellent in shock and allied conditions, as stated above. Chapin has employed cold enemata in the diarrheas

of children to aid in the reduction of temperature, and with success. Cold irrigation has also been employed in dysentery for this purpose with good results. Cold irrigation might be employed in sthenic cases to reduce temperature, if used with caution, for five to ten minutes. Friction of the limbs during its application would be advisable, as during the Brand bath. He states that he would not care to employ at the start a temperature below 60° to 70° F. He refers to high intestinal irrigation. It would probably be safer also to use it at first for only two to three minutes.

On the other hand, he has seen benefit in jaundice (duodenal) from the cold irrigation briefly employed (two quarts), or from the alternate hot and cold douche (two quarts each) for chronic constipation. A glass Y-attachment, as suggested by Dr. John Minor, is suggested for this purpose.

Cold rectal irrigations are much safer, and he has seen iced water so applied for thirty minutes in a congestive condition of the rectum, and with great benefit. Some, however, have a marked idiosyncrasy to cold of any degree, and it should therefore be employed with caution.

Hare reports a rise of 4° to 5° F. in dogs after twenty minutes' irrigation, with a temperature of 115° F.; also a marked fall of temperature, practically shock, after the use of cold for twenty to thirty minutes. He does not state whether or not the animal was covered, nor the temperature of the room; which facts make a considerable difference.

The writer states that his own experiments agree with Hare's in regard to the cold, but differ in degree, as regards the effect of the heat on the temperature—quantitatively, not qualitatively—in the result. He believes that without doubt the prolonged irrigation has, at the high temperatures, an influence on the body temperature. The cold irrigation, when prolonged, is undoubtedly depressing.

In ten minutes irrigation at the higher temperatures, especially at 110° to 120° F., stimulates the kidneys to secretion by the heat, and by the stimulating effect on the circulation, also by the heat, blood flows through the organs.

In twenty minutes, irrigation at 100° to 120° F. causes excretion from the kidneys actually through absorption from the intestines, as is shown by potassium ferrocyanide experiments.

Dr. L. Bolton Bangs has administered ene-

mata of iodide of potassium and secured reaction in the urine in twenty minutes.

Clinically, hot saline irrigation is an excellent remedy in uremic suppression, or in cases of renal insufficiency.

Dr. Egbert Grandin has had excellent results from this procedure, and has been advocating it for some time past. Dr. William H. Thomson has employed it with success when other means have failed. They both report excellent results, profuse sweating and bowel action accompanying the renal secretion. Dr. Thomson has employed saline irrigation at 101° to 104° F. with gratifying results recently in an obstinate case of renal insufficiency where other remedies were a failure.

Renal disease with polyuria as a symptom would seem to contraindicate this method, or that it should be cautiously used and for short periods. This statement has special reference to a case of enlarged prostate, in which prolonged irrigation was employed. It aggravated the polyuria and had to be stopped.

It will be specially noted that no reference has been made to the effect of cold irrigation on renal secretion or intestinal absorption; for Kemp considers it a dangerous procedure. Experiments were made in this regard, but the author has kept them apart. Enemata of cold water at different temperatures will be absorbed from the intestines and, as in experiments with hot saline with potassium ferrocyanide, urinary reaction will occur in about twenty minutes, giving the blue with chloride of iron. On the other hand, cold irrigation will for a short time stimulate the circulation and increase secretion, but in about twenty minutes pulse tension will fall, the animal will go practically into shock, and renal secretion cease. We will thus have renal suppression plus shock, or be worse off than before, and the cold will aggravate the suppression.

Cold irrigation is absolutely contraindicated in renal disease—also cold enemata.

---

*THE CLINICAL VALUE OF DIPHTHERIA  
ANTITOXIN ADMINISTERED  
PER OS.*

ZAHORSKY, of St. Louis, concludes as the result of some experiments that diphtheria antitoxin acts similarly whether given by the mouth or subcutaneously, but its effect occurs much later when given in the former way.

It is possible that the intestinal epithelium

refuses at certain times to take it up, and therefore it is a less reliable method.

This mode should be employed in mild cases when objections stand in the way of its hypodermic use. It may be also used in mild cases in adults.

Its use by the mouth as a prophylactic measure is to be recommended, as it presents many advantages. However, if the child has been exposed to diphtheria for as much as two days the hypodermic method should be employed.

Joint pains, erythema, urticaria and dysmenorrhea are not prevented.

From a clinical standpoint, therefore, it is to be urged that for curative purposes the administration by the mouth should be restricted to exceptional cases; but for prophylactic purposes this method should receive the preference.

---

*THE LOCAL TREATMENT OF PAINFUL  
ULCERATIONS BY ORTHOFORM, WITH  
SPECIAL REFERENCE TO THE  
UPPER AIR-PASSAGES.*

YONGE writes of this new drug in the *British Medical Journal* of February 5, 1898. The anesthetic presents a triple claim to recognition, in that it is sparingly soluble, is non-toxic, and is powerfully antiseptic. On the other hand, it is a disadvantage that the substance will not act on unbroken skin, nor, with certain reservations, on intact mucous membranes, for its strong anesthetic properties are only manifested where nerve endings are exposed. The slow solubility leads the anodyne to exert its action economically on the tissues, and unlike its rapidly soluble congener, cocaine, only sufficient is dissolved to produce and keep up local insensibility, which therefore becomes prolonged. In from five to ten minutes after application anesthesia of the denuded surface to both touch and pain commences, and it reaches its consummation within a short period of time. The effect lasts from a few hours to five or six days, and there is, in the majority of cases, perfect or nearly perfect analgesia, the patient experiencing the sensation of the offending part having been cicatrized over or "enameled." Suppuration is usually markedly diminished and healing accelerated.

The action of orthoform on the unbroken mucous membrane of the mouth, nasopharynx and larynx is, in the author's experience, as follows: Neither the free orthoform (basis powder) nor the hydrochloride anesthetic sufficiently to allow of surgical action. When

applied to the tongue, inner surface of the cheek, or to the pharynx, a numb sensation supervenes in the course of about five minutes, but there is little real anesthesia. The effect on the larynx is to reduce reflex irritability. A peculiar feeling, described as similar to that produced by cocaine, is experienced in five minutes; in a few more minutes this relative loss of sensation vanishes, but if before its subsidence a probe be introduced and the vocal cords and interior of the larynx touched, although a species of "gagging" ensues, there is no laryngeal spasm or cough. In the same patient a similar procedure without the previous introduction of orthoform causes intense discomfort and a fit of coughing. The intact nasal mucous membrane is also slightly amenable to the influence of the drug. A feeling of numbness is evidenced in about two minutes, and this merges into real anesthesia, which is, however, feeble and transient.

Yonge has had the opportunity of testing the anesthetic value of orthoform in eighteen patients who suffered from painful ulcerations of the upper respiratory tract, and a few representative cases are quoted.

Toxic effects were not noted in any of the cases, but there was occasionally some slight burning for a few minutes after the application of the hydrochloride. This failure to discover toxicity is compatible with the statements that over twelve drachms has been sprinkled on a broken surface in the course of a week, also that thirty to sixty grains have been administered to rabbits, and forty-five to ninety grains to dogs, without evil effects during life or the post-mortem discovery of visceral changes. Orthoform fails to produce any results on an ulcer unless the dual precaution is taken to apply the drug directly to the loss of surface and to insure its retention there.

No relief was experienced by patients suffering from either catarrhal pharyngitis or quinsy.

The antiseptic action of orthoform appears to be demonstrated by the rapid diminution of purulent exudation in several of the cases encountered, and the speedy healing of the ulcer. In a case of acute gonorrhea injections of orthoform solutions were followed by the disappearance of gonococci in four days, and the complete cessation of blennorrhagia.

Finally, if further observations confirm the results already published, it would appear that orthoform is entitled to take a position

among the local anesthetics applicable to the upper air-passages. It seems probable that it will replace—by virtue of its insolubility and innocuousness—its relative, cocaine, when long anesthesia on ulcerated surfaces is wished for.

#### LOCOMOTOR ATAXIA IN ITS MODERN ASPECT.

F. M. LANGDON tells us in an article contributed to the *Medical Record* of January 8, 1898, that in the modern treatment of tabes the old idea of giving "alteratives," mercury and potassium iodide for their (doubtful) absorbent effect on cicatricial tissue is giving way to measures addressed to the nutrition of the neuron.

There being no syphilitic exudation in true tabes, antisyphilitic treatment is uncalled for. Diet, hygiene, rest, are the main factors in the successful management of the disease. Digestion, assimilation, elimination, must be promoted. Climate, medicines and electrotherapy are of distinct value.

Distressing symptoms, the "lightning pains," "ataxia," etc., are to be alleviated without impairing the general nutrition. Opium had better be avoided.

Rest in bed is a valuable measure when obtainable. The patient should sleep much and work little. When complete rest is not practicable, a few extra hours daily in the horizontal position is advisable.

The diet should be liberal—meats, fats, milk, water in abundance, and fruits, with a minimum allowance of starchy and saccharine foods. Alcohol is to be prohibited.

The patient should wear warm clothing, and if possible spend his winters in a warm climate. Measures addressed to the elimination of auto-toxins generally by the skin, kidneys and bowels should be instituted.

Drugs of more or less use in the treatment are those of nutritional value, mainly phosphorus, iron, cod-liver oil, with tonics such as strychnine.

For the lightning pains aluminum chloride (dose, two to four grains in water) is a drug of considerable value. Dr. Gowers originated its use for this purpose.

Electricity is of distinct value in a large proportion of cases. Ordinary faradism is useless, galvanism better. The writer's experience has led him to value highly that form of electricity known as the "sinusoidal" current. It is a current of "high potential" (voltage), rapid alternation (480 to 1920 per second), and comparatively small "quantity"

(amperage). Its application is simple and controllable, as well as pleasant to the patient. It is administered by means of a "foot-plate" and a neck electrode for from five to fifteen minutes every alternate day for six weeks. Under its use, with simple hygiene and often without drugs, the lightning pains cease, the ataxia of gait and station disappears, and the well-being of the patient is promoted. These effects would seem to indicate an actual improvement in the nutrition of the peripheral sensory neuron, with capacity for better function in some, possibly restoration of damaged nerve endings in others. This six weeks' course of treatment may be repeated once or twice yearly, as indicated, with advantage to the patient.

Patients treated by the foregoing methods have been under observation for nearly two years without relapse of pains or ataxia, and with full capacity for ordinary business affairs. All cases are improved, some more than others, depending on the stage and extent of the disease. Many additions to cases formerly cited might be made, but space and time forbid.

In conclusion, it may be stated that, by reason of clearer conceptions of its pathology, leading to a more rational therapy, locomotor ataxia becomes a more hopeful disease to treat.

#### TREATMENT OF LUPUS BY CONCENTRATED LIGHT.

N. R. FINSSEN, of Copenhagen (*Semaine Médicale*, 1897, No. 59), who some time ago published an account of the red-light treatment of variola, has now utilized the light rays, which he found so injurious in smallpox, in the treatment of lupus vulgaris. The action of light as a disinfectant and bactericide has been recognized by many investigators, especially recently by A. Ransome in regard to tubercle bacilli. It is, therefore, very interesting to hear that Finsen, by means of a simple apparatus, has concentrated the rays—either sun rays or electric arc rays—on patches of lupus, and in most cases has obtained satisfactory results. R. L. Bowles has pointed out that the rays at the violet end of the spectrum—or "chemical rays," as they are termed—probably penetrate more deeply than do rays in other parts of the spectrum, and one would think that the almost translucent material of lupus granulations would be more suited to transmit them than ordinary skin. There seems nothing improbable in the view that the con-

centrated light rays, at least the "chemical" ones, actually reach the tubercle bacilli which cause the cutaneous affection, and gradually kill them if the lupus granulations be not too opaque. Finsen's paper is illustrated by some of the results he has obtained.—*British Medical Journal*, Jan. 29, 1898.

#### THYROID TREATMENT IN INSANITY.

GERVER (*Obosrenye Psichiatryiek*, November, 1897) has tried the effect of Poehl's thyroidin in ten cases of insanity. The patients included three cases of acute primary dementia, three cases of melancholia, one case of recurring mania, one case of delusional insanity, one case of organic lesion of the brain, and one case of epilepsy. To begin with, two grains of thyroidin was administered twice daily, and the dose gradually increased to ten grains given three or four times a day. The treatment was continued for about six weeks, but in one case, that of organic cerebral lesion, it had to be discontinued earlier, as it caused too much gastrointestinal disturbance. The result of the trial was disappointing. Only two of the patients benefited by the treatment, and even in them some doubt was felt whether the improvement was due to the thyroidin or whether it occurred in the natural course of the disease. The successful cases were one case of melancholia in a lady, aged seventy-two, in whom the disease disappeared a year previously without any thyroidin treatment, and the case of delusional insanity in a middle-aged man, who stated that he felt the strong stimulant effect of the thyroidin. During the treatment some peculiar physiological effects of thyroidin were observed in all the patients. Their pulses were increased, and they all lost weight. The temperature, sleep, and appetite were unaffected. Salivation was observed in one case, and twitchings of the facial muscles in another.—*British Medical Journal*, Jan. 29, 1898.

#### THE LITHOTOMY POSTURE IN PARTURITION.

Dr. OSCAR SCHMIDT, of Moscow, contributes an article on this subject to the *Centralblatt für Gynäkologie* of November 27, 1897. He says that he has made use of this posture for about eight years past, employing it while the head is in the pelvic cavity and when it is at the outlet. The patient lies on her back, lengthwise of the bed, and at the beginning

of a pain two persons, usually the physician and the midwife, standing one on each side of the bed, seize the patient's legs, bend her knees to the utmost, spread them apart as much as possible, and flex the thighs on the pelvis as in the lithotomy posture, at the same time everting the toes. That one of the physician's hands which is not employed in holding a knee may make pressure upon the child's breech, and so strengthen the action of the abdominal muscles. When the pain subsides, the limbs are allowed to resume their natural posture in the bed. The author thinks the favorable effect of this procedure is demonstrable. In the case of a primipara, he says, the segment of the fetal head that appears at the vulva during a pain is much larger than when she simply lies on her back. The difference is seen most strikingly in multiparæ when the head is in the pelvic cavity, and often very few pains with the woman in the lithotomy posture suffice to complete the birth. Almost without exception, says Dr. Schmidt, the patients take kindly to this procedure, and he has even observed, in cases in which it was an object to delay the expulsion of the child, so that he has omitted to resort to it, that the patient herself would assume the posture voluntarily during the pains, holding her knees with her own hands. He adds that since he adopted this device the occasions of his having to resort to the forceps operation, either high or low, have been reduced to a minimum, and almost without exception they have been brought about by pathological conditions.

Dr. Schmidt thinks there are several reasons why this posture facilitates the process of parturition. In the first place, he says, it increases the intra-abdominal pressure, but, what is of greater consequence, it enlarges the pelvic outlet. He refers to experiments made by Walcher, and others by Klein, accounts of which were published respectively in 1889 and 1891, showing that the articulations of the pelvis, especially the sacroiliac, possessed a certain degree of mobility. With the sacrum fixed, the symphysis pubis may be moved up and down a little. The center of rotation is situated behind and beneath the promontory of the sacrum. The authors mentioned, says Dr. Schmidt, gave their chief attention to the conjugate diameter of the pelvic inlet, as being the most important obstetrically, but Klein measured the transverse diameter also. The conjugate diameter of the pelvic outlet, says Dr. Schmidt, the distance from the tip of the

coccyx to the lower border of the pubic symphysis, unfortunately, is not mentioned by them, and the same is true of the transverse diameter, the distance between the tubera ischiorum. We know, says the author, that when the symphysis sinks as much as it can the conjugate diameter of the inlet is increased; when it is raised as much as it can be, as in the lithotomy posture, that diameter is diminished. It follows as a logical consequence, he thinks, that the reverse must happen to the conjugate diameter of the outlet. Whether or not there is at the same time a greater separation of the tuberosities of the ischia, he adds, has not been directly ascertained; in only one of Klein's experiments on corpses was such an effect shown, and that but to a small extent. However, Dr. Schmidt himself believes that it does occur, judging from the fact that in cases of symphyseotomy the maximum separation of the pubic bones is obtained by resorting to the lithotomy posture. The same thing has been observed by Biermer in experiments on the dead body. The tendency of the pelvis is, therefore, to expand laterally in this posture; unfortunately, as yet no measurements of the degree of pelvic mobility in the dead bodies of freshly delivered women have been made. The pelves that Klein dealt with did not include one of a pregnant or lying-in woman, and so we may explain the fact that his observation of the comparatively small change in the conjugate diameter on changes of posture does not tally with the observations of clinicians. We are leaning more and more, says Dr. Schmidt, toward the view of the old obstetricians, that Nature makes the pelvis movable for parturition; Driver observed the fact in three hundred lying-in women.

The lithotomy posture has been employed in labor by others. Dr. Schmidt refers to its use by Remy, who has the patient lie crosswise of the bed, and straps her thighs to her body with two bands of sticking-plaster. The author thinks his intermittent method must save the woman some discomfort. Especially in primiparæ, he says, in whom there is so often a disproportion between the size of the head and that of the vulva, compelling the physician to resort to the forceps, it cannot fail to be an advantage to have at command a procedure that the patients regard as a "natural" mode of delivery. Frequently a unilateral incision answers in cases in which the forceps might do great injury to the vagina and perineum.—*New York Medical Journal*, Jan. 8, 1898.

*THE INJECTION OF STERILIZED OLIVE OIL WITH GUAIACOL AND IODOFORM IN TUBERCULOSIS.*

A. BRETON, of Dijon, publishes an article on this subject in the *Journal des Praticiens* of December 19, 1897. He first calls attention to the fact that he published an article upon this topic during the last year, in which he reported 550 injections of sterilized olive oil with guaiacol and iodoform. The formula which he employs is:

- ℞ Iodoform, 15 grains;
- Guaiacol, 75 grains;
- Sterilized olive oil, 3 ounces.

One to one and a half drachms of this is injected at a dose and, he asserts, without danger. He records 424 injections given to eighteen patients suffering from pulmonary tuberculosis, and claims that the effects are distinctly favorable. He also records the history of nine of these patients, giving more minute details as to the results which he obtained. These consist chiefly in showing that there was an amelioration of all the pulmonary symptoms and a general increase in weight. The injections should be given into the loose connective tissues of the back, or shoulder, or thigh.

Careful asepsis should be maintained. Two patients who were suffering from diarrhea developed a scarlatiniform eruption after the guaiacol had been employed. This erythema was intensely itching and lasted three to five days in its acute phase, with slight fever, but entirely disappeared eight or nine days after the injection. Breton is inclined to believe that the intestinal disorder was responsible for it.

---

*MUSHROOM POISONING.*

There is only one rule to be followed in avoiding poisonous mushrooms, and that is to know that the particular variety is safe because it has been eaten with impunity. That is, the one who picks mushrooms should be able to say that he knows a kind to be good, not because it has this or that characteristic, but because he recognizes it as one that he has tried. He should know it in the same way that he knows he is picking blueberries or whortleberries and not the berries of the deadly nightshade. Those who go by any rule of thumb, such as the color of the gills or the presence of rings on the stem, or still more by such crude tests as the discoloration of a silver fork cooked with the mushrooms, will be likely to come to grief sooner or later.

It is to be remembered first of all in dealing with the subject of mushroom poisoning that these fungi are easily decomposed, and being largely nitrogenous may readily become the cause of ptomaine poisoning. Murrell warns particularly against this and urges that great care should always be taken that mushrooms are fresh when cooked; to warm them over he considers a dangerous practise. Ptomaine poisoning from mushrooms would be like that from the development of tyrotoxicon in milk products, and would take the form of an acute gastro-enteritis beginning within a few hours after the ingestion of the poison.

Quite different from this is the typical mushroom poisoning, whose cause as far as is known is muscarine, first described by Schmiedeberg as a colorless, syrupy mass, without odor or taste, and easily soluble in water or alcohol. An account of six cases of this form of poisoning was given last summer by Dr. Caglieri, of San Francisco; it illustrates well the peculiar delay in the action of the poison. The six cases all occurred in one family and three were fatal. The mushrooms were eaten at about six in the evening. The first symptoms appeared in all the cases during the forenoon of the following day, and took the form of vomiting and diarrhea. In most of the cases these symptoms were slight. All felt dull and stupid on awakening, and there was a feeling of dyspnea which led them to seek the fresh air. One patient, a child, died during the evening of this day with convulsions. The two others who died (also children) showed no serious symptoms until the morning of the second day. At this time there was mental dulness increasing to stupor, rapid, empty pulse, contracted pupils, irresponsive to light, rapid respiration, suppression of urine, and free perspiration. One died on the second, one on the third and one on the fourth day after the poisonous meal. The fatal dose in all of these cases was but a small one—in two cases but one-half of a medium-sized mushroom, and in the third case but one-sixth. The members of the family who escaped ate as much or more of the mushrooms, and it is supposed that there were but one or two poisonous fungi in the dish; that those who died ate these, while the others ate good mushrooms that were rendered somewhat poisonous by being cooked together with the bad. Muscarine is present in the dry fungus of the commonest poisonous variety (the *Amanita*) in the proportion

of only one-fifth of one per cent., so that the fatal dose, which has never been accurately determined, must in the light of these cases be a small one.

The physiological antidote of muscarine is atropine, which should be given in full dose, say one-sixtieth of a grain, and repeated if the pupils are not dilated by the first dose. With this should be given strychnine and such other stimulants and heart tonics as are usual in the treatment of poisoning by depressants.—*Northwestern Lancet*, Jan 1, 1898.

#### THE TREATMENT OF DELIRIUM.

The *Medical News* of February 26, 1898, contains an article by COLLINS on this topic, in which, after wandering over a very large subject, and touching here and there some of the more important points, he makes a few direct remarks on the treatment of delirium, fully cognizant that therapeutics must vary in every case, and that the indications in one kind of delirium may not suffice or be sufficient in another. Nevertheless, there are a few underlying principles in the treatment of all deliria, and it is these which he endeavors to lay down, prefacing his remarks by saying that sedatives are used too frequently and too indiscriminately. Bromides especially are frequently given offhand, in large doses, and over quite an extended period, apparently forgetful of the fact that they may, by adding to the vascular depravity which is so often at the bottom of the delirium accompanying asthenic states, intensify and prolong the duration of the symptoms for which they are given.

The general indications in the treatment of delirium are, first, to secure sleep; second, to overcome motor unrest; third, to prop up and maintain the patient's vitality by contributing to his nutrition; and fourth, to discover and remove the cause upon which the delirium is dependent.

To meet the first indication hypnotics are almost always required, although it should never for a moment be forgotten that an hour's sleep induced by measures taken to fulfil the third condition is far more salutary than three hours' sleep obtained by the use of a hypnotic. Moreover, that in many forms of asthenic delirium, whether the asthenia be induced by infection, intoxication, exhaustion, senility, or what not, sleep is more readily induced and maintained by measures directed immediately against the asthenia than against the insomnia. In the selection of a hypnotic

the one least depressant to the patient's vitality and least apt to be followed by depression should always be given preference. The motor depressants should never be used in the delirium accompanying the asthenic state, except as the very last resort. In certain forms of sthenic delirium, and especially those in which a sedative effect cannot be produced by the external application of water, drugs which are motor depressants and at the same time hypnotics may be used with the greatest benefit. Of these, the alkaloids of *hyoscyamus* are the most available.

The second principle is that great care should be exercised in the application of mechanical restraint in all forms of asthenic delirium, lest the encroachment on respiratory capacity lead to pulmonary complications which jeopardize the life of the patient. Whenever possible, physical restraint is very much less dangerous.

Concerning the third principle, that of maintaining the patient's vitality, Collins insists on its importance.

The meeting of the fourth indication, viz., the discovery and removal of the cause of the delirium, is after all the most essential procedure in the treatment of this symptom. To do this the pathological association must be determined, and then our ammunition leveled directly against it, while simultaneously the first three principles enumerated are guiding us in symptomatic therapy.

#### METHYLENE BLUE IN MALARIAL FEVER.

The Berlin correspondent of the London *Lancet* of February 26, 1898, tells us that Dr. Cardamatis, of Athens, inspired by the researches of Professor Ehrlich of Berlin, and Professor Boinot of Paris, has successfully used methylene blue in the treatment of malarial fever. In his report communicated to the *Deutsche Medicinische Wochenschrift* he publishes 275 cases where the drug was administered. The dose was from ten to twelve grains ("Gran") for adults, eight grains for younger patients, six grains for children, and one or two grains for infants at the breast. In typical intermittent fever the drug is given ten hours before the beginning of the paroxysm; in remittent or continuous fever eight hours before the remission. When both methylene blue and quinine failed a combination of the two drugs proved useful, but the effect was less marked when the methylene blue was associated with arsenic. The

combined treatment was necessary in only thirty of the 275 cases. In quotidian ague, when the patients had become free from fever, after five days' administration, the drug was given for six days. A pause of two days followed, after which it was again given for four days; after a second pause of eight days there was a final administration spread over two days. After twenty-two days a radical cure was obtained in this way. When the attacks appeared again after the fifth day treatment was continued for forty-eight days with several interruptions. In tertian and quartan ague the first stage of the treatment lasted twelve days, and the remedy was given for sixty days with several carefully arranged intervals.

The advantages of methylene blue were especially obvious in those cases where quinine had proved useless or where there was intolerance of it. The drawbacks associated with methylene blue are the staining of the tongue and the lips; a slight amount of cystitis was also sometimes observed, but these inconveniences are very slight in comparison with the radical cure obtained in nearly every case. Immunization seemed to be produced by the treatment, for although the convalescents continued to reside in the malarial district very few of them indeed were subsequently attacked. With the exception of the cystitis already mentioned no toxic symptoms were ever observed. In eighteen instances the fever disappeared after the first day, in thirty-six after the third, in eighty-four after the sixth, in eighty-eight after the tenth, in eighteen after the eleventh, and in thirteen after the twelfth day. In eighteen cases no cure was obtained. In thirty-eight out of the 275 cases a relapse occurred after two months.

#### THE COLD-BATH TREATMENT OF SCARLET FEVER.

In a recent number of the *Blätter für Klinische Hydrotherapie*, JURGENSEN, of Tübingen, writes on the value of the treatment of scarlet fever, from the moment of its invasion to the end of the disease, by means of cold baths. As soon as the temperature reaches  $102\frac{1}{2}^{\circ}$  the patient receives a bath which lasts for about five minutes, the temperature of the bath being about  $80^{\circ}$  or lower. Children well advanced in years may have even colder baths with advantage. Jürgensen claims, with Leichtenstern, that by this means the pulse is slowed, the temperature

is reduced, and that a very favorable influence is exercised upon the general circulatory and nervous system. The baths may be repeated every four or five hours, but seem to be particularly valuable in those cases where the system is depressed by the toxemia of the disease. Where the physician fears that the shock to the patient will be disadvantageous, warm baths may be used, the temperature being as high as  $100^{\circ}$  to  $106^{\circ}$ , and, at the same time that active frictions are applied, cold affusions should be made to the head and shoulders.

The following contraindications to this method of treating scarlet fever are named: Feebleness of the heart or existence of appreciable myocarditis, difficult respiration due to stenosis of the air-passages, epistaxis or hemophilia, inflammations of the joints. Where scarlatinal nephritis is to be treated, hot baths at about  $100^{\circ}$  to  $102^{\circ}$  or hot packs may be used to advantage to relieve the kidneys.—*Revue de Thérapeutique Médico-Chirurgicale*, Feb. 1, 1898.

#### MASSAGE IN THE INCOERCIBLE VOMITING OF PREGNANCY.

In the *Bulletin Général de Thérapeutique* of December 15, 1897, JEFFROI, while recognizing the fact that a large number of remedial agents have been employed in the treatment of this condition, strongly recommends massage. He states that usually it only requires five or six seances to obtain a complete result, and after two or three rubbings the vomiting ceases. The massage is applied to the region of the stomach and duodenum. Nearly always there will be found when it is begun marked tenderness in this region. He reports a number of cases in which this treatment was followed by very good results.

#### THE TREATMENT OF ACNE VULGARE AND ACNE ROSACEA.

The local treatment of acne vulgaris may be by means of scarification, but care should be exercised in its use lest permanent and severe cicatrices result. After scarification compresses wet with a solution of one-half to one per cent. of lysol may be applied. At night an ointment containing ten per cent. of precipitated sulphur and two per cent. of pure resorcin and salicylic acid may be applied after the part has been washed with green soap. Should this treatment cause

great irritation of the skin, this may be partially removed in the morning by a cooling ointment or cold cream. After some time, when the treatment has, by producing inflammation, substituted desquamation for the ordinary acne process, the part may be dressed with one of the following ointments:

- ℞ Ichthyol, 5 grains;  
Oxide of zinc and starch, 75 grains;  
Vaseline, 6 drachms.

Or,

- ℞ Oxide of zinc,  $\frac{1}{4}$  ounce;  
Olive oil,  $\frac{1}{4}$  ounce.

The following ointments may be applied to the skin in cases of acne rosacea, being thoroughly rubbed in:

- ℞ Naphthol, 15 grains;  
Washed sulphur, 1 drachm;  
Vaseline,  $1\frac{1}{4}$  drachms.

Or,

- ℞ Pure resorcin,  $\frac{1}{4}$  to 1 drachm;  
Oxide of zinc and starch, of each 15 grains;  
Vaseline, 2 drachms.

Should the skin be very red and turgescient it may be well to aid total desquamation of the skin in the region treated. Under these circumstances the prescription given for oxide of zinc and sweet oil may be used to allay the inflammation. Sometimes the prescription for ichthyol already named will be useful. In very rebellious cases scarification may be needed, under which circumstances anesthesia may be produced by the use of chloride of ethyl. — *Revue de Thérapeutique Médico-Chirurgical*, Feb. 1, 1898.

#### THE HYDROTHERAPY OF MEASLES.

In the *Blätter für Klinische Hydrotherapie*, JURGENSEN recently published an article upon the bath treatment, dealing in this case with the disease, measles. As a rule he does not believe that hydrotherapy is necessary, but should the following conditions arise it is useful: Should the patient be stuporous, or if there be marked delirium and convulsions, cold affusions at 60° to 70°, lasting for two minutes, may be applied to the head and neck. If this is insufficient to reduce the temperature, then a bath of 70° to 80°, lasting for five minutes, with colder affusions to the head, may be used. Feebleness of the heart does not seem to be the same contra-indication to the use of cold in measles as it is in scarlet fever. Should there be signs of laryngeal stenosis it may be well to place the child in a hot bath or in a hot pack for from

fifteen to twenty minutes. Should the face become very much congested, cold affusions may be applied to the head or an ice-bag may be used. Should the temperature become subnormal, a hot bath may be given accompanied by energetic rubbing. Where there are evidences of catarrhal bronchitis it may be well to apply sudden cold affusions to the chest and to follow these immediately afterwards by the administration of an emetic.

#### THE NON-OPERATIVE TREATMENT OF ENDOMETRITIS.

The *Journal de Médecine de Paris* of February 6, 1898, gives the following advice under this heading: The vagina and the cavity of the uterus is first thoroughly washed by a 1-to-1000 (!) solution of corrosive sublimate. After this one of the following crayons is introduced:

- ℞ Powdered iodoform,  $2\frac{1}{2}$  drachms;  
Gum tragacanth,  
Glycerin and water, sufficient quantity to make 10 crayons.

Or, instead, salol or resorcin may take the place of iodoform.

Sometimes the following treatment can be used:

- ℞ Corrosive sublimate, 7 grains;  
Powdered talc, 1 ounce;  
Gum tragacanth,  
Glycerin and distilled water, a sufficient quantity to make 15 crayons.

These crayons may be introduced into the uterus and kept there by tampons saturated with iodoform or salol, which are placed in the vagina.

[We should regard this treatment with doubt, preferring in all cases curettement or other operative procedure.—Ed.]

#### ON THE TREATMENT OF SOME OF THE MORE COMMON EYE AFFECTIONS.

In the *Edinburgh Medical Journal* for January, 1898, Mr. BERRY gives the following information as to some of the common eye affections:

A condition that one is frequently called upon to treat is hyperemia or inflammation of the lid margin. The inflammation, blepharitis, is met with in very varying degrees of severity, and leads to more or less marked ulceration of the free margin of the lid, as well as sometimes of the contiguous skin. Different cases of blepharitis are often classified according to differences in the local

pathological changes. From the point of view of treatment it seems better to recognize, as far as possible, the main differences in etiology. A sufficiently useful etiological classification might embrace three groups, which, however, can hardly be said to be always absolutely distinct.

One of these groups includes the cases of blepharitis which occur for the most part in delicate children, and are often associated at times with attacks of phlyctenular inflammation of the conjunctiva and cornea. Some reference has already been made to these cases. They are cases of what may be called the strumous form of blepharitis. Another group includes the cases which are more or less evidently connected with a chronic catarrhal condition of the tear sac. The last group again comprises those of herpetic or eczematous blepharitis, as the third variety has sometimes been called. In these there is an absence of the strumous element, and usually, at the same time, of any evidence of auto-infection from local sources. They mostly occur in adults, and are often associated with more general eczema of the skin of the lids.

The worst cases of blepharitis belong to the first two groups. The inflammation in them often goes the length of ulceration, and this ulceration leads to greater or less destruction of the eyelashes. In old-standing cases it is common, indeed, to find a complete or practically complete absence of eyelashes. This gives rise to an ugly, red, blear-eyed appearance, which is very characteristic. Short of this there may be an alteration in the color and character of the lashes, many of those remaining being misdirected, and thus leading sometimes by their inversion to irritation or ulceration of the cornea. The ulcers of the lid margin, as they extend in depth, partially or completely destroy the hair follicles, and then cause these changes in, or the loss of, the eyelashes.

In the treatment of all cases of blepharitis, the first step should be to remove the crusts or scabs which have formed, and to epilate, with the cilia forceps, all the eyelashes which present a distinctly abnormal appearance in their color, their thickness, or the direction of their growth. The subsequent treatment must depend upon the etiology of the local inflammation, as well as to some extent upon the severity of the changes which have been produced. Sometimes, when the ulcers of the lid margin have become to a great extent confluent, a really satisfactory clearing of the soil for local applications can only be got by

first cutting all the lashes off with a pair of scissors. This is comparatively seldom necessary, however. Before attempting to remove the scabs, it is best, in the more pronouncedly impetiginous cases, to apply a starch poultice, in order to soften them. They can afterwards be carefully and thoroughly picked off with a piece of quill, without causing much pain. Until this is done, any epilation that may be required should not be begun. Besides saving trouble, owing to many of the diseased lashes coming away with the scabs, it is then easier to see from the little ulcer pits which lashes it is advisable to pull out. When from the raw surface thus exposed there is found to be an exudation in which there is an evident admixture of pus, which is only rarely the case, and only in the strumous variety of blepharitis, it is well to paint the lid margin over once with a five-per-cent. solution of nitrate of silver, dabbing the solution well into the ulcers with the camel's-hair brush. This should be followed up by the use, three or four times daily and for a quarter of an hour or so at a time, of compresses soaked in a one-half-per-cent. solution of the neutral subacetate of lead. After these have been used for a few days, recourse may be had to the yellow oxide ointment. When the blepharitis is associated with phlyctenular conjunctivitis or keratitis, it is best to use the mercurial precipitate, according to the prescription already given. If it exists alone, the following preparation may be used instead:

℞ Hydrargyri oxidi flavi, grs. x;  
Vaselini albi, 3 ss.

This should be well smeared along the lid margin morning and night.

Occasionally from neglect, or owing to some particularly marked delicacy on the part of the patient, often from both combined, and always in young children, the lid margin inflammation is not only ulcerative, but is associated with a great deal of deep infiltration, so that the tissues of the lid, and especially the tarsus, are much swollen and thickened. In such cases the ordinary treatment is of no use. As the eyelash follicles are then irretrievably destroyed, and there is consequently no use attempting to save them, the best treatment is to freely scrape away the ulcerated tissues with a small Volkmann spoon, and then undermine the skin and transplant it over the comparatively healthy raw surface which is left.

The general treatment in the case of the

strumous variety of blepharitis should be on the same lines as that already discussed in connection with phlyctenular keratitis. Dark glasses should be worn outside in summer, and also in winter when there is snow on the ground. The skin should be kept clean by frequent baths, and cod-liver oil or syrup of the iodide of iron given internally.

In a number of cases of less severe blepharitis, which do not rapidly improve by the use of the yellow oxide ointment, efficiently applied after the scabs and crusts and diseased eyelashes have been removed, it becomes advisable to slit up the canaliculi. This should always be done, as already explained, when any regurgitation of mucus or muco-pus can be got by pressure over the tear sac. But whether such regurgitation be found or not, the little operation is indicated wherever a blepharitis exists for a long time on one side alone. In such a case it often happens that the blepharitis rapidly disappears without any further treatment, although it may previously have resisted other therapeutic measures. There is not, however, the same justification for early interference of this kind in bilateral cases. In them it should not be undertaken, unless there should either be definite evidence of a catarrhal state of the mucous membrane of the tear passages, or a decided rebelliousness to the treatment recommended above.

The eczematous variety of blepharitis, besides being practically only met with in adults, never assumes the impetiginous type which characterizes so many cases in strumous children. Hyperemia of the lid border with a scaly crusting, and sometimes a sort of herpetic eruption, are the appearances presented by this form. In the milder degrees the lid margin has a look almost as if it had been dusted over with flour, although the numerous small scales are hardly as white.

The treatment should consist in frequent bathing with warm water, the lid margins being well rubbed with a wet pledget of cotton-wool. A little zinc ointment may also be smeared on in the morning after the bathing. The following ointment may be used:

℞ Zinci oxidi, grs. viij;  
Vaselini albi, 3 ss.

Or, the crusts may first be rubbed off with the cotton-wool soaked in a little spirits and water (about one part of whiskey to three of water), and then the following ointment rubbed in:

℞ Ichthyoli, ʒ ij;  
Aque destillatæ, f 3 ss;  
Lanolini, 3 ss.

Attention should be paid to the conditions under which the eyes are used, and sources of irritation, such as dust or smoke or impure air, as far as possible removed. Dark glasses are also sometimes useful. Further, it is always advisable to correct any existing error of refraction, especially for near work. In troublesome cases it is well to recommend an anti-gouty diet. It is especially important to knock off alcohol, especially if, as is often the case, it happens to be more freely indulged in than necessary.

A condition which is often complained of, and generally more on account of its unsightliness than for any great discomfort to which it gives rise, is a sort of blind pimple of the lid margin. Usually there is only one, though occasionally there may be several, elevations of this kind at different parts of the margin. The pimple appears as a uniformly red conical elevation. Its base occupies mostly the portion of the flattened lid margin which is in the neighborhood of its free outer edge. Often there are epithelial squames at other parts, indicating a slight degree of blepharitis, but this association may be quite absent. These pimples occur mostly in adults, and often in cases which present more or less evident arthritic symptoms.

The question of treatment has most often to be considered in the case of ladies, who are often sensitive as to the disfigurement which the condition causes. No doubt there may be some degree of local discomfort as well. The actual disfigurement depends partly upon the size, of course, but mainly on the degree of congestion which the little prominences present. The natural duration of the pimples is variable. They may only last a few weeks, but often remain in much the same state for many months. Usually, however, in the chronic cases, the redness, which at first is marked, tones down to a great extent, so that the adventitious tissue assumes nearly, if not quite, the color of the rest of the lid margin, and consequently becomes much less apparent. On everting the lid there is always found to be a little circumscribed area of hyperemia of the conjunctiva, roughly triangular in shape, with its base directed to the portion of the lid margin on which the pimple has formed. In chronic cases there is always to be seen a yellowish streak coursing down the middle of the hyperemic patch. This is simply a Mei-

bomian duct blocked with secretion which has become more or less calcareous. Even in recent cases it is usual to find a degree of transparentness in the middle of the congested conjunctival area, behind which some whitish secretion in the duct shows itself.

The treatment consists in emptying out this retained secretion. This can be done at first by simply pressing the affected portion of the lid between the two thumb nails, which causes the natural exit at the lid margin to burst open and give escape to a sebaceous-looking secretion. In cases which have lasted for some time it is necessary to incise from the conjunctival surface, making the cut along the yellow streak referred to, and up to the base of the pimple, and then to press out the contents. The pimple itself in either case then quickly disappears. In recent cases it almost immediately loses its hyperemia, and this of itself is always a cause of satisfaction to a patient who has been mainly annoyed by the unsightliness which it has produced. Not infrequently there are found to be other little patches in the lid of the same nature, though rarely as large, but which are not complicated by the protrusion at the margin. These should be treated in the same way, and preferably at the same sitting. An astringent lotion may be used for some time afterwards.

#### THE TREATMENT OF ARTICULAR RHEUMATISM.

The following formulæ are given in the *Revue de Thérapeutique Médico-Chirurgicale* of December 13, 1897: Absolute rest in bed and a diet consisting exclusively of milk, broths and eggs, hot drinks in abundance, and in each liter of liquid thirty grains of the nitrate of potassium. Envelop the affected joints with an ointment, applied after the following liniment has been rubbed in:

- ℞ Laudanum,  
Chloroform,  
Olive oil, equal parts.

The ointment should consist of ten per cent. of salicylic acid with lanolin. Internally the salicylate of sodium may be given in the dose of one to two drachms a day. This should be kept up for two days, when it should be slightly decreased. Full doses are, however, necessary. There are several ways of administering it: First, in cachet. This is a method which is not to be recommended, as it is apt to irritate the stomach. The same

difficulty exists with solutions of the drug. A useful formula is as follows:

- ℞ Salicylate of sodium, 3 drachms;  
Rum, 1 ounce;  
Syrup of orange flowers (bitter),  
Distilled water, of each 3 ounces.

A dessertspoonful to a tablespoonful of this at a dose. Sometimes the salicylate of sodium may be given by rectal injection. Thirty grains of it is placed in four ounces of water and given once, twice or three times a day. Before the injection is given the bowels should be well washed out. The contraindications to the use of salicylate of sodium are alcoholism, pregnancy, arteriosclerosis, old valvular cardiac lesions, cerebral rheumatism, and nephritis. In some cases where the salicylate of sodium is contraindicated, salophen may be given in the dose of forty-five to seventy grains in cachets. Antipyrin, while it does not cure the rheumatism, may be used to relieve the pain in doses varying from ten to forty-five grains a day. It may be given in solution in ordinary water or in Vichy, or by means of rectal injection.

#### A NEW OPERATION FOR THE RADICAL TREATMENT OF CANCER OF THE CERVIX, CONSISTING OF THE REMOVAL OF THE UTERUS AND VAGINA EN MASSE BY THE SUPRAPUBIC METHOD.

WERDER writes in the *American Journal of Obstetrics* for March, 1898, detailing his methods. He thinks that the radical operations as ordinarily performed for the cure of malignant disease of the uterus are, to say the least, unsatisfactory, as is shown by the large percentage of recurrences within a comparatively short period, and by the number of modifications in the technique recently recommended by different operators for the purpose of improving our permanent results. That the cause of failure is largely due partly to our inability to operate in strictly healthy tissue in cancer of the cervix, especially when extensive and involving the greater part of the vaginal portion, and partly to an inoculation of healthy tissue with cancer cells during the course of operation, the author thinks can be demonstrated by the fact that in the large majority of cases the disease returns in the vaginal cicatrix left as the result of a hysterectomy, whether vaginal or abdominal. Such, at least, has been his experience in all the cases in which he was able to observe the subse-

quent course of the disease. In order to obtain better results it is, therefore, essential to do more radical work at the seat of disease, viz., the cervix and vaginal fornices, which are in contact and frequently more or less extensively involved in the disease. It is these latter particularly—*i.e.*, the vaginal fornices—which cannot always be removed to a sufficient extent to insure operating in absolutely healthy tissue by the ordinary vaginal or suprapubic methods of hysterectomy, on account of the proximity of the bladder, rectum, and ureters.

For some time the author has been convinced that the removal of the vagina, or at least its upper portion, with the uterus is the only method which enables us to completely extirpate the diseased parts in cancer of the cervix. It occurred to him that the technical difficulties connected with such an operation could be successfully overcome by opening the abdomen, severing the uterus as in ordinary hysterectomy, and freeing the bladder from it; with this difference, however, that the dissection is extended down along the vagina, separating the anterior wall of that canal from the bladder as far down as we wish to remove the vagina. The recto-vaginal space is then entered, and the posterior vaginal wall is stripped off the rectum as far down as necessary; finally the lateral attachments of the vagina are loosened. The uterus and vagina having thus been entirely freed, that organ could be pushed down into the pelvic outlet, the vagina being inverted by making traction from below until it could be amputated above the prolapsed fundus. All this could be done without touching the diseased cervix with the fingers or allowing it to come in contact with any wound surfaces, thereby absolutely excluding the possibility of inoculating healthy tissue with cancer elements.

The feasibility of the operation briefly described above having been tested and confirmed in the post-mortem room, an opportunity for its practical execution presented itself on the living subject January 5 of this year.

The patient, Mrs. D., aged forty-five, mother of four children, the youngest of whom is nineteen years old, was referred to the author by Dr. C. M. Cameron, who had made a diagnosis of cancer of the cervix in February, 1897, almost a year ago, and advised operation, which was, however, refused until hemorrhage and a very fetid discharge compelled her to get relief. When she came

under his notice she was anemic and weak. The vaginal portion of the cervix was the seat of a cauliflower growth completely filling up the upper portion of the vagina and invading the anterior vaginal pouch. The uterus, however, was still movable, and parametria free. Radical operation seemed, therefore, still indicated and advisable. It would have been exceedingly difficult to keep at a safe distance from the diseased area in the vagina, especially at the anterior vaginal wall, in the usual vaginal or suprapubic hysterectomy, and the case seemed especially suited for the operation under consideration.

The patient having been anesthetized, the whole vaginal portion was very easily removed by a sharp spoon curette, as it was completely broken down by the disease. The remaining bleeding surface was seared over with the thermocautery. The patient was then prepared for laparotomy. Both ovaries and tubes were found adherent, and the left tube distended with about an ounce of creamy pus. After the ovarian arteries were secured the bladder was separated, not only from the uterus, but also from the broad ligaments on either side as far as possible, so as to get the ureters out of the way. This opened up both broad ligaments, and the uterine arteries could be easily traced over to near the pelvic bones, where they were tied without difficulty. An assistant having inserted two fingers into the vagina as guides, the dissection between bladder and vagina was then carried down to within about an inch of the vulva. The sacro-uterine ligaments were then divided with scissors, the rectum separated from Douglas' pouch, and, with two fingers, the dissection extended down to the lower half of the vagina. The lateral walls of the vagina were then freed from their attachments. The uterus and vagina were now only held by the base of the broad ligaments, which were very firmly bound to the vaginal fornices, the separation of which formed the only really difficult part of the operation. This having been accomplished and the broad ligaments completely divided, the finger could be passed all around the uterus and vagina, and at no place had the vaginal tube been opened. The loss of blood during the whole operation was insignificant. The uterus and vagina were then pushed down into the pelvic outlet, and the bladder with its peritoneal flap drawn across the pelvic cavity and stitched over the rectum to the posterior wall of the pelvis, thereby completely shutting off the pelvis from the general peritoneal

cavity and covering up all raw surfaces with the peritoneum. The abdomen was closed in the usual manner.

The operation having been done in the Trendelenburg posture, the patient was now placed in the ordinary lithotomy position. The uterus, which was protruding at the vulva, was seized with vulsella forceps and drawn completely out of the vulvar orifice with the inverted vagina. With a finger in the rectum and a sound in the bladder, as safeguards against injuring those organs, the inverted vagina was amputated with the thermocautery.

An inspection of the cavity showed a large raw cavity lined in front and above by the bladder, behind by the rectum, about four inches of which was completely exposed, and below by a very short vagina. The cavity was lightly packed with gauze and the patient returned to bed. Duration of operation, two hours.

The specimen consisted of the uterus with the right ovary and tube attached, the left one, filled with pus, having been removed earlier in the operation, to prevent soiling the field of operation. To the cervix was attached at least two inches of the vagina. The patient was suffering from considerable shock, from which she recovered rather slowly. After the third day, however, her condition became entirely normal, and her convalescence was interrupted only by a slight parotitis, which subsided in a few days. Examination of the pelvis on the tenth day showed a very small cavity above the remaining vagina, observed with healthy granulations, in which the bladder and rectum were no longer recognizable.

The operative technique the author found much easier than he had anticipated, and not more difficult than a total abdominal hysterectomy. After a little experience he thinks it should not consume more time than the latter operation. He would suggest the use of rubber gloves for the preliminary curettement, to keep the hands aseptic and to avoid contact with cancerous tissue, thereby not only preventing any danger of septic contamination, but also excluding with absolute certainty the possibility of inoculation.

The operation seems an ideal one for the treatment of cancer of the cervix, because we can do a more radical operation than by any other method, and we can remove that part which, on account of its proximity and anatomical relation to the original seat of disease, is earliest invaded, but by our pres-

ent methods most difficult to reach. It should give more permanent cures, even in advanced forms, because we can not only extirpate the vagina or as much thereof as may be deemed necessary, but we can excise the greater part of the broad ligaments if we take the precaution to carefully push aside the ureters with the bladder. It enables us also to get at the iliac glands without much additional trouble or difficulty, should we regard their removal as necessary.

---

*OPERATION FOR THE RESTORATION OF  
THE URETHRA AND FOR THE  
CLOSURE OF A VESICO-VAGI-  
NAL FISTULA INVOLV-  
ING THE NECK OF  
THE BLADDER.*

C. P. NOBLE tells us in the *American Journal of Obstetrics* for March, 1898, that operations for the closure of vesico-vaginal fistulæ have been so perfected that the closure of such fistulæ, at one time the despair of surgeons, can now be accomplished with the certainty of success in almost all cases, even those involving the most extensive destruction of the base of the bladder. Fistulæ involving the neck of the bladder are among the most difficult to close, and cases complicated by destruction of the urethra have long taxed the ingenuity of surgeons. Fortunately, such cases are rare, and but few gynecologists, even those of extensive experience, have met with them. Probably Dr. Emmet has had a larger experience in dealing with such cases than any other operator. He states that he has succeeded in restoring the whole urethra by plastic surgery in six or seven cases, and only partially so in others. Emmet portrays most vividly the difficulties of these operations, and states that he is less inclined than formerly to operate upon them because of the slim chances of success or permanent benefit from such procedures. Olshausen reports three cases in which he has performed the operation of restoring the urethra. In two of the cases he was successful, but the third was a failure. The author has not had time to make a careful search through medical literature for all the operations reported, but there is no doubt that the number is small. The following case has come under his own observation, and he reports it as an encouragement to others to attempt the cure of similar injuries:

Mrs. S., aged fifty-two, white, American, the mother of three children, had had good health until 1896. Nothing in her history

bears upon the subject of this report. At the age of forty-nine she noticed, especially when tired, a throbbing, referred to the rectum. On account of the continuance of this symptom, in March, 1896, she consulted a physician in Reading, Pa., who stated that an immediate operation was required to prevent invalidism. The operation was performed and was followed by some leakage of urine, which became profuse after the removal of the stitches on the eighteenth day. The primary operation was said to be for the removal of a "blue spot" on the anterior vaginal wall. In the attempt to repair the opening in the bladder the doctor operated seven times. Four of the operations were performed without general anesthesia. From the patient's statement it is apparent that various suture materials were employed in the different operations, including harelip pins; after some of them a drainage catheter was used, and after others it was not employed. All of the operations failed. At this time a mass projected through the fistulous opening, which she was told was a polyp, and it was proposed to remove this. She then consulted her family physician, who told her that the supposed polyp was the prolapsed wall of the bladder. This resulted in the discharge of the doctor who had made the fistula, and, upon the advice of her family physician, a well known gynecologist was called in, who operated upon her twice in Reading and twice in a hospital in this city. Union was not secured.

Mrs. S. consulted the author November 16, 1897, and on examination he found that the entire inferior wall of the urethra was gone and that a fistula existed involving the neck of the bladder. The situation of the urethra was marked by a strip of mucous membrane continuous above with the vesical wall. The opening into the bladder was large enough to admit the index-finger. The edges of the fistula were cicatricial, and upon each side of the urethra extensive cicatrices were present, probably the result of incisions made at the various operations to relieve tension on the sutures. After some of the operations there must have been considerable destruction of tissue, as a large amount of cicatricial tissue was present.

The mental condition of the patient was very bad, being due, doubtless, to the failure of the eleven operations to effect a cure and to the constant annoyance of the discharge of urine. November 20 the author operated upon her at the Kensington Hospital for

Women. As a preliminary he procured a Sims sigmoid metallic catheter, whose diameter was one-third that of the usual catheter. The operation was performed as follows:

An incision was made along the edge of what corresponded to the original mucous membrane of the urethra, from the meatus to the bladder. External to this line of incision a raw surface was made upon each side of sufficient breadth to make a firm urethral wall. The edges of the fistula into the bladder were then denuded, an effort being made in the denudation to secure as small a neck to the bladder as possible. Deep incisions were then made, parallel to the long axis of the vagina, upon each side of the proposed urethra, to secure flaps out of which to form the new urethra. On the left side it was necessary to detach the soft parts entirely from the pubic bone in order to overcome tension.

The sutures were introduced in the following manner: The small catheter was introduced and held in position; over this was sutured, with a running suture of No. 1 cumol catgut, the mucous membrane of the bladder and that of the new urethra; interrupted silver-wire sutures were then introduced to close the opening into the bladder and to form a new urethra. An effort was made to pass the sutures at the neck of the bladder in such a way as to catch, if possible, the muscular fibers which form the sphincter vesicæ. The silver-wire sutures were then twisted and tightened, closing the fistula in the bladder and building up a new urethral wall. To reenforce this line of sutures, and to secure an even better approximation, a silkworm-gut suture was placed between each of the silver-wire sutures. Sutures were then passed in the direction of the axis of the vagina to close in part the incisions made at each side of the restored urethra, and more especially, by approximating the ends of these incisions, to still further guard against tension on the restored urethra. The deep incision on the left side was then packed with gauze. The operation lasted about one hour and a quarter.

The next problem was to secure healing, and the author determined to leave the catheter *in situ* until the newly formed urethra had firmly united. After two days the catheter became blocked by a deposit of urinary salts, after which time the bladder was washed out daily with boracic acid solution to overcome this difficulty. The catheter

ter remained *in situ* until the twelfth day, after which it was removed daily for cleansing. The line of union healed by first intention throughout, although the tissue which made up the left side of the restored urethra was cicatricial in character and its vaginal aspect was bare of mucous membrane. Three weeks after the operation the deep incisions had filled up by granulation and only a small area remained for cicatrization.

The patient is able to retain her urine for from three to five hours, after which time she has not perfect control over the bladder and is apt to discharge a small quantity of urine if the bladder is not promptly evacuated.

The author would like especially to call attention to two points in the technique of the operation, as he believes a successful result was dependent upon them. The first was the use of a very small catheter, which was left in position until primary union had been secured. He felt, and still feels, certain that an attempt to pass a catheter through a somewhat distorted canal daily or more frequently would result in the perforation of the canal and failure of the operation. The second point was the method used in suturing. By first restoring the mucous lining of the canal with a continuous catgut suture, it was possible to insure a narrow urethra of uniform diameter, and in the subsequent restoration of the wall of the urethra it was possible to disregard the urethral canal and to consider merely the building-up of a firm urethral wall. It was possible also to study the problem of tension more carefully. It was found necessary to make a very extensive detachment of the soft parts from the pubic arch in order to secure a flap of tissue without tension.

---

THE ASCH OPERATION FOR DEVIATIONS  
OF THE CARTILAGINOUS NASAL  
SEPTUM, WITH A REPORT  
OF TWO HUNDRED OP-  
ERATIONS.

MAYER writes in the *Medical Record* of February 5, 1898, on this topic. He begins by telling us that deviations of the cartilaginous septum may be of recent origin, or they may have existed for a long time. If of the former class, they are invariably due to some form of violence, while in the latter they may have other causes due to some faulty development, being practically congenital in their origin.

When they are of recent origin the surgeon is most apt to be consulted. If of long standing they are generally discovered by rhinologists in their search for the cause of the train of symptoms complained of and which they occasion. These symptoms are mainly permanent obstruction to respiration on one side, mouth breathing, dryness of or excessive secretion in the throat, constant rasping, fitful sleep, nasal voice, epistaxis, aural diseases, diminished hearing, persistent headaches, and many reflex disturbances. It frequently happens that the patient is not aware of the nature of the diseased state which causes his complaints.

Deviation of the cartilaginous septum may be defined to be a deflection from the normal straight line to one side, filling the nasal cavity more or less completely, accompanied by a corresponding depression on the side opposite. For simplicity of description the deflected or obstructed side is called the convexity, the other the concavity. It offers no difficulties in the way of diagnosis, and can be ascertained to exist by either or all of the following methods: Obstructing the nostril on the concave side and requesting the patient to blow—either no air or a very thin stream is felt upon the hand. Reversing the procedure, a full, free current is obtained. By dilating the nostril with a speculum, or even raising it with the finger, the deviated portion is readily seen, the convex side filling the nasal space. Touching with a probe reveals its firmness. Cocainizing produces no retraction, and usually the probe, having passed beyond the obstruction, readily enters the nasopharynx.

Perforations occur in about two per cent. of the operated cases, are usually about the size of a pin's head, and are caused by the curling up and sloughing of the edge of one of the segments. In no single case was there any alarming hemorrhage, either at the time of operation or subsequently. No septic conditions resulted, no disagreeable after-effects; no disturbance traceable to the operation occurred, nor was there at any time any danger to life. These results are the more remarkable in that these operations were performed upon dispensary patients, whose physical conditions are rarely of the best.

There are two separators, one with a blunt edge and the other sharp, to break up any adhesions existing between the septum and the turbinate on the affected side, as also to destroy any posterior obstructions. The scis-

sors are of two sizes. These are powerful instruments, curving outward from the point of crossing and meeting again in front. One blade is blunt, while the other is sharp with a triangular blade, the apex of which is at the tip. The other scissors are made with the blades bent at right angles, and are occasionally necessary for those deviations that lie low down on the floor of the nose.

There are two compressing forceps, one having a long and the other a short beak.

Hollow tubes of vulcanite are made with a slight curve on the under surface, in accordance with the normal curve at the entrance of the vestibule of the nose. These tubes have perforations to prevent their slipping out when inserted. They are of different sizes and shapes. Those known as the Asch tubes are of five sizes, somewhat oval in shape, and those known as the Mayer tubes are of six sizes, more oval, and considerably flatter on the sides. These vulcanite tubes are so prepared that they retain their shape when subjected to the heat of a sterilizer.

The operation is best performed under complete anesthesia. Cocaine does not appear to be of value here, it being necessary that the patient be recumbent, and in the efforts to dislodge the blood flowing into the pharynx the operator is seriously interfered with. The nose is sprayed out immediately preceding the operation, for which purpose an alkaline antiseptic, like the Dobell solution, is used. The usual preparations for anesthesia are made, ether or chloroform being the anesthetic used. All instruments are carefully sterilized. The use of an antiseptic spray and the sterilization of instruments for an operation when the air cannot be excluded either before or after operation may be explained by stating that we know that by such care we are surely not adding any infection by our operative procedure. Complete anesthesia is required. The cone being removed, it never becomes necessary to have recourse to it again, as the operation is rapidly performed and completed before consciousness is regained.

The head is well drawn backward, in order that blood may not enter the larynx, the table being so placed that either the direct or artificial light may be used.

The blunt separator is now introduced sideways on the deviated side, in order that any adhesions existing between the septum and its adjacent mucous membrane may be broken up, enabling us at the same time to ascertain the presence of bony obstructions

posteriorly. Should these latter exist or the adhesions be non-yielding, the separator with sharp edges is required; this, however, is rarely necessary. There may be some hemorrhage after the adhesions are broken up, but it is readily checked by an iced spray, or by pressure of cotton applicators. The open scissors are now introduced parallel to the floor of the nose, the blade in the concavity, the blunt edge over the point of greatest convexity. They are then firmly closed, the blade cutting through the cartilage into the opposite side with a distinct snap. The scissors are then opened and completely withdrawn. They are immediately reintroduced, the direction of the instrument being upward this time, pointing to the frontal bone, the blade being in the cavity and crossing the line of the first incision at as nearly a right angle as possible, and at its center. In this way the incisions will intersect each other. The scissors are now firmly closed and the second incision made, after which the scissors are opened and withdrawn.

We now have four segments as a result of this crucial incision. The finger is then introduced in the deviated side and the segments are forcibly pushed into the concavity, effectually breaking them at their base.

The powerful blunt forceps is now introduced, one blade in each nostril, and firmly closed, thus straightening the septum and forcing the broken segments to override each other in the concavity. The compression aids also in controlling hemorrhage, and the parts are firmly held in apposition. An iced antiseptic solution is sprayed in both nostrils, the forceps being withdrawn. The sterilized tubes are then introduced in the nose, a snugly fitting one on the stenosed side and a smaller one in the opposite nostril, thus causing equable pressure, their presence being usually all-sufficient to control hemorrhage. The operation is now completed. The amount of blood lost varies with each individual, but is invariably promptly checked when the pressure is applied.

The patient is placed in bed, cold antiseptic sprays are used half-hourly, and iced cloths are applied externally.

Twenty-four hours after operation the tube in the formerly concave side is withdrawn and not replaced. The antiseptic spray is used once every hour or two and the compresses are continued. Twenty-four hours later the tube on the stenosed side is removed and

thoroughly cleansed. The nose is freely sprayed and cleansed with cotton probes, cocaine being used if sensitive. The same tube is reinserted, unless too large for comfort, when a smaller one is used, the rule being to use a tube large enough to be introduced without force, and yet to fill the cavity, no part of it protruding from the nostril. On this day patients are permitted to arise from the bed and assume other than a recumbent posture, the compresses being discontinued. On the third day the tube is again removed, cleansed, and reinserted, and the patient allowed to go home. For the next three or four days the patient presents himself daily for the removal, cleansing, and reinserting of the tube. At each time of removal the nose is thoroughly cleansed and freed from secretions and clots. Within the first week the patient has learned to extract and reintroduce the tube himself, in the presence of the surgeon, and thereafter performs it once or twice daily at home. The directions are given to remove the tube, spray out the nose, or insufflate warm salt water to which an alkaline antiseptic is added, and then to reintroduce the cleansed tube. The extraction and reinsertion of the tube are quite painless after the first week, and it is remarkable how easily the youngest patient becomes accustomed to it. The patient is now seen once or twice a week for the next four weeks, at the end of which time—five weeks from the day of operation—the tube is finally withdrawn for all time.

The mass of bent cartilage has disappeared, the septum has become straightened and remains so, and very often the external deformity no longer exists.

Sometimes during the five weeks that the tube is in it may appear that the septum is bulging greatly on the stenosed side, but it is well to leave it quite alone, as the constant pressure reduces it finally, for there seems to be a resorptive process going on.

It occasionally happens that the lower segment remains thickened after the five weeks have elapsed, and presents the appearance of a spur or enchondrosis. This is treated as such and removed by the electro-trephine or galvano-cautery. The latter has worked splendidly in the author's hands, especially in nervous individuals and children. The parts are cocaineized and then cauterized with a platinum knife. There is no bleeding and the patient is not aware of any operative procedure. A light packing of iodoform or subli-

mate gauze is introduced daily for the next few days after cauterization.

During the five weeks that the tube is in place, excepting the first three days, the patient resumes his usual vocation—children go to school, and adults find no interference in their work.

The segments which were pushed into the concavity, thus destroying the resiliency of the cartilage, overlap each other, become firmly adherent, and in a short time there is no evidence of any unusual condition whatever.

The advantages of the tubes can hardly be overestimated, establishing comfort at once by allowing air to pass through, and acting as splints to keep the septum straight; the readiness with which they are removed and reinserted making them infinitely superior to the original method employed of packing with absorbent cotton about a tin splint.

---

*A CASE OF RESTORATION OF THE FEMALE URETHRA AND CLOSURE OF THE BLADDER, AFTER EXTENSIVE LACERATION.*

In the following case, reported by RICHARDSON in the *Boston Medical and Surgical Journal* of March 3, 1898, Thiersch's principle, used in restoring the urethra in cases of epi- and hypo-spadias in the male, was successfully employed. This principle is applied to the female urethra and bladder, and consists in the use of extensive flaps superimposed in such a manner that the internal surface of the urethra and bladder is supplied by vaginal mucous membrane; at the same time the denuded vaginal surface is restored by shifting a flap sufficiently large to cover it.

The patient, Mrs. M., aged twenty-six, had had in May, 1897, a very difficult labor. The attending physician found a deformity of the bladder and an exaggerated hymen. There had never been any penetration. With the patient on the table in the dorsal position, no opening in the hymen could be found. The child was delivered with difficulty and with the use of instruments.

After confinement there was inability to control the bladder. On examination the author found an entire absence of the urethra. There was in its place an irregular line of everted mucous membrane extending a half inch back into the base of the bladder.

A flap was first made to the patient's right of the fissure and corresponding to it in

length. The base of this flap was the line of everted mucous membrane. Turned toward the left, this flap presented its mucous surface upward, and was destined to be the floor of the urethra. The second flap, on the patient's left, was a little longer than the first, and began at the left edge of the everted urethra. This flap had its base about half an inch to the left of the urethra. A catheter was next placed in the urethra, and over it the first flap was spread. This flap was fastened to the denuded surface of the second flap by four silk sutures. The catheter was covered in by vaginal mucous membrane. The second flap was then brought over the first and to the right, where it was fastened by numerous fine silk stitches.

It will be seen that mucous surface was brought to mucous surface, and raw surface to raw surface. Immediate union resulted without leakage. The patient not only had a tight bladder, but she could control it. Since operation there has been no loss of control, but micturition is frequent, especially when she is erect.

This method of closing the fistula presents a double chance for success; for if the mucous approximation is imperfect, as it is likely to be from the impossibility of using sutures, the denuded surfaces, opposed to each other over comparatively broad areas, can be most closely approximated and accurately sutured.

The author has used the method very successfully in restoring the male urethra. The difficulties in applying it to the female are somewhat greater, for in addition to the restoration of the canal the power of controlling the bladder through the sphincter vesicæ is essential. In this case the functions of this muscle were completely restored.

#### THE MEDICAL AND SURGICAL TREATMENT OF HARELIP.

MUMFORD reminds us in the *Boston Medical and Surgical Journal* of March 3, 1898, that no two cases of harelip are alike. They vary as much as do the faces which they deform; and so, from the simple notch in the border to the double harelip with complete cleft palate, each case must be treated on its own merits. And yet they have not been so treated; nor have the operators, in many cases, seemed to appreciate the importance to the individual of a natural and slightly mouth. As to the child's parents, they are easily satisfied and but too well pleased to have a

hideous cavity bridged over in any fashion. With all these varieties of deformity, however, there are two main divisions for surgical purposes: those lips which are backed by a sound jaw, and those which are continuous with the nostril and a palatal cleft. In the former class the mortality is *nil*, so far as the lip is concerned, whether treated or not. In the second class the mortality is high when untreated—by some writers placed as high as thirty per cent.; when treated the mortality ranges from two to fifteen per cent., according to Fritzsche. These deaths are ascribed in all cases to malnutrition, hemorrhage, or bronchitis. In the author's opinion, by very far the most important factor is malnutrition. We hear of harelip babies, vigorous, puny, well nourished, and rachitic; and the appropriate time of treatment for each. As a matter of fact, most of these babies are well enough at birth, and their subsequent condition depends largely upon the care and intelligence used in their feeding. If this care be used, the average infant can be brought comfortably up to the sixth or eighth week—the proper time for a harelip operation. Operations done earlier must be hurried and ineffectual for cosmetic purposes; if done later, except in the simple cases, the advantages of an early molding of the nose and lateral pressure upon a cleft upper jaw are in a measure lost.

This highly important preparatory feeding of the patient is in itself an art, and if outside the experience of the surgeon, should be entrusted to some one skilled in infant feeding. In the author's experience its successful prosecution influences very largely the result of the subsequent operation, and its effects are felt even up to the period of dentition.

Ordinarily there is no difficulty in giving the modified milk mixtures prepared in the laboratories for infant feeding. These mixtures with an alkalinity of five to six per cent. answer all practical purposes. When milk laboratories are not accessible, home modification may be done.

In administering the milk there are a few practical hints which should be borne in mind. The food is best fed from a spoon; the various shields and patent nipples are needless and troublesome. The child should be placed on the bed in a half-reclining position during feeding, because when prone the milk is more likely to run up into the nares. If there is a cleft palate, the most scrupulous care must be observed to keep clean the mouth and nares; for this a cotton

stick dipped in a weak boric acid or borax and water solution is best. Plenty of clear water to drink should be given between feedings, as the mouth necessarily is very dry, and by the use of the water a proper action of the bowels is maintained. Stimulants should be given if there is pallor or a flabby skin—one or more drops of brandy with each feeding. The brandy should be increased for two days before operation, and on the day of the operation, in any case, a goodly measure should be allowed.

Most authorities are now agreed that chloroform is the best anesthetic for the operation, on account of its non-irritating action on the lungs. This may be so; but in some considerable experience with ether the author has seen no cause to complain of it, and he sees to it that it is properly given. He likes its stimulating effect.

As to the time for the operation itself, he makes one exception to the rule he lays down. In simple notched lips not extending to the nostril, he thinks it well to wait until the child is three or four years old, as he can then be trusted to manage the wound carefully, and a most exact plastic operation can be done with the more mature tissues.

In these cases, and indeed in all others, so far as ultimate beauty of result is concerned, the greatest attention must be paid to the finish of the vermilion border. For this purpose the Nelaton or Malgaigne operations are the only ones to be used. The old-fashioned slashing cuts with scissors, and the quick sewing up, are bad surgery, and should never be used except when desperate hurry is demanded.

There is a large variety of other flap operations described by authors—Hagedorn's, Mirault-Langenbeck's, Simon's, Giralde's, and many more. They are all designed on the dove-tail principle, their object being to fill in the cavity and provide a smooth, red-lip border. In practise the author does not think them applicable to infant lips. They sometimes answer admirably for older children and adults, but not for restless, crying babies. At best, they leave an irregular scar instead of a straight line, and there not infrequently results an ugly notch in the lip border.

It is not necessary here to go into the treatment of the intermaxillary bone. Suffice it to say that it can usually be forced into position and utilized. In very rare cases it must be sacrificed.

It has been claimed by some writers that

double harelip operations should be postponed until the second or third year of life, but the author prefers to do them within the first two months, if possible, for he is convinced that the same advantages apply to the early operations in these cases as to those of single harelip. In all operations, except for a simple notch, the soft parts about the alveolar processes and nares should be dissected free from the upper jaw with blunt-pointed scissors. By clinging closely to the bone, no hemorrhage will result. When the flaps are being cut the coronary arteries may be controlled easily by an assistant's fingers. Scissors should not be used in cutting the flaps. They are inaccurate, sometimes bruise the tissues, and do not leave so clean and broad a cut surface. A narrow-bladed knife is best.

The old-fashioned harelip pins have gone out of use, and very properly. Even when removed on the third day—the old rule—they leave a scar; and the third day is too early for the removal of deep sutures. In all operations, for both double and single harelip, one shotted stitch of silver wire is sufficient to anchor the parts. It is inserted in the fold behind the alæ, lies in that natural furrow, takes all the strain off from the severed deep parts, holds in place the intermaxillary bone, and leaves no perceptible scar. When this stitch has been placed and the parts approximately brought into position, the question of passing the remaining stitches is one simply of time and patience. In all extensive operations, and always in the case of babies, the author has adopted the method of J. C. Warren. Working with a stout silk suture, threaded with a needle at each end, the stitch is entered close under the skin, in the freshened lip border, is passed deeply through the underlying soft parts and buccal mucous membrane, and tied strongly to its fellow inside the mouth. Three or four of these heavy stitches suffice to hold the parts firmly in excellent apposition; when tied, the ends should be cut long. The slight gaping in the skin flaps of the external wound is closed with a few very fine intestinal sutures threaded in small embroidery needles, and are passed as closely as possible to the cut edges, the greatest care being taken not to draw them tight enough to invert the skin. The fine superficial sutures must be removed on the third day, and it will be found that no perceptible stitch scar results. The deep stitches are removed from the inside of the mouth on the fifth or sixth

day, and the wire bridge on the seventh or eighth day.

By no means the least part of the operation is the application of a proper sustaining strap from cheek to cheek. The old-fashioned adhesive plaster is a wretched device, and should never be used; it is unclean, sweats the parts, and checks any discharges which may collect. The familiar *crêpe-lisse* "butterfly" is the best support. It is light, clean, slightly, and does not check discharges. Before applying it, it is well to paint the wound inside and outside the mouth with compound tincture of benzoin, to lay a soft absorbent pad across the external wound, and then firmly to secure the "butterfly" with flexible collodion.

Silkworm-gut is sometimes used for sutures. It is applicable only when tied outside the lip. When so used it always leaves a scar.

For older children and adults, the author has had most excellent and satisfactory results with buried catgut. By its use only can an approach to an aseptic operation be made. The firm resisting tissues of an adult offer an excellent hold for the buried stitch, and if there remains a slight gaping of the skin it can be closed with the fine intestinal sutures.

An absolutely aseptic programme can never be carried out in any harelip operation, but some attempt should always be made to render the field approximately sterile. The constant use of boric acid washes both before and after operation should be maintained. At the time of the operation the upper lip should be thoroughly wiped over, inside and out, with alcohol, which in its turn is to be washed off with water.

During convalescence, especially after the removal of the stitches, some spreading of the upper part of the wound should not discourage the surgeon. As a rule, if the vermilion border holds, the open cleft above will heal, by the second intention, in two or three weeks. There is often a very anxious time about the end of the first week, but the holding of the border is a sure sign that all will yet go well.

No one feature in the whole treatment of harelip is of more importance than that of the feeding of young infants during convalescence from the operation. As an immediate result of the operation there is almost always a considerable gastro-intestinal upset. This is in part due to the anesthetic and in part to

shock, but by far the most important factor is the blood which has been swallowed. No matter what the form of operation or the position in which the child is held, a very considerable amount of blood finds its way into the stomach. If this is vomited, so much the better; but usually it remains and makes trouble. There then follow several days of diarrhea, undigested stools, pain, colic, sometimes loss of appetite, and occasionally vomiting. These symptoms may persist many days and do not infrequently most seriously threaten life. More often, however, they merely debilitate the patient, and seriously delay the healing of the wound. He has seen cases in which a total lack of success in closing the lip was obviously due to a low vitality in the wound through malnutrition in an infant hitherto perfectly healthy and strong.

Of the very greatest importance, therefore, is proper care during convalescence.

The ordinary rules for the treatment of an acute mycotic diarrhea are here applicable. On the evening after the operation a brisk purge should be given—castor oil or calomel; and the child should be put on a weak cream mixture. Sometimes even this is not borne, and a thin barley-water mixture or weak, strained chicken tea should be substituted for it. Meanwhile liberal doses of brandy should be given, and if diarrhea persists, bismuth subgallate, in three-grain doses or more, should follow each feeding. Gradually the diet may be strengthened as convalescence progresses, until the normal mixtures have been reached. At the same time plenty of water to drink should be given—a precaution most often neglected by uninstructed nurses.

A *résumé* of the important points in the treatment of harelip, therefore, will include the following considerations:

1. Harelip babies are not necessarily feeble at birth, and by proper feeding can be kept up to the normal standard.
2. Keep the field clean with aseptic washes before the operation.
3. Operate in the sixth to the eighth week.
4. Do not slash with scissors, but cut and trim carefully with a knife.
5. Free the upper lip thoroughly from the jaw.
6. Anchor the nares with shotted wire.
7. Use no pins or heavy outside sutures.
8. Use *crêpe-lisse*, not surgeon's plaster.
9. Leave the heavy inside stitches for six days.

10. After operation give especial attention to the care of the bowels and to proper feeding, as on this very often hangs the whole success of the operation.

#### FRACTURES OF THE SKULL.

POPE in the *International Journal of Surgery* for April, 1898, points out that fractures of the skull are not uncommon accidents, and present for consideration: (1) Trauma in its various modes of action, producing fractures of various kinds and degree; (2) local sequelæ such as hemorrhage, exudation, and inflammation; and (3) post-traumatic nervous sequelæ.

Complicated and compound fractures of the skull present danger in two directions: (1) danger that arises from direct injury to the brain and its membranes, and (2) danger of infection of the wound from within or without.

Trauma acting upon the skull usually affects the cranium in two general ways, with variations: (1) Local depressed fractures occupying a reasonably small area. Those fractures are, as a rule, not compound, and become so when they are produced by some sharp instrument. (2) Extensive fractures of the vault or base that are produced by trauma, so directed as to bring about a bursting effect, and in their results we find widespread injury to the brain and membranes.

Danger from serious fractures of the cranium, be they simple or compound, lies not in the fracture itself, but in the injury to the nerve elements or their destruction by subsequent infection or in the production of subsequent neural trouble, such as focal epilepsy. One of the latest works upon surgery, and another upon neurology, distinctly advise, if moderate symptoms of cerebral trouble develop, or if the cerebral symptoms are subsiding, or if they are known to be present, the treatment should be "expectant" (?), and interference by trephining should never be resorted to until the development of the later cerebral symptoms. Compound fractures, as a general thing, are opened and cleaned, trephining not often resorted to, especially in fractures of the base where expectant treatment is carried out; and the author's experience, limited though it be, and considered largely from the neurological standpoint, is against delay in operative interference. Trephining under aseptic precautions is in no sense a dangerous operation, and we can feel safe in desperate cases

that the relief in intracranial pressure will help the patient. Summing up shortly his experience on the subject, he says:

1. Operate in all cases of fracture of the skull, basilar or compound, and preferably in simple fractures.

2. Expectant treatment, in his opinion, is dangerous, permitting injury to the nerve structures.

3. Danger does not exist in fracture *per se*, but in subsequent injury to the nerve elements and tissues.

4. Failure to trephine and immediately remove the existing pressure, depression, hemorrhage, inflammation, or septic infection may result in the development of focal epilepsy and other cerebral diseases.

5. Little or no danger results from the operation.

6. These rules are doubly applicable to fractures of the base, owing to the danger to vital structures lying there.

#### THE SURGICAL TREATMENT OF MALIGNANT DISEASE OF THE LARYNX.

BRYSON DELAVAN, of New York, writes in the *Journal of the American Medical Association* of March 12, 1898, on this subject. He thinks that while operations for the cure of malignant disease of the larynx have generally resulted in shortening rather than lengthening the lives of patients so operated upon, the experience of the past few years in certain parts of the world has been somewhat encouraging. Indications are beginning to appear which suggest that for this class of patients there exists a not entirely unpromising future.

Within the past two years several papers have been published in which the proportion of successful operations has been unusually large, and while the actual number of patients operated upon has been too small to establish any positive conclusions, and the dates of most of the operations have been too recent to admit of a complete study of the cases themselves, there can be no question that the work recorded in them is, on the whole, worthy of careful consideration. The varieties of operation which have lately challenged attention by reason of the improvements which they have offered may be divided into three groups: (1) thyrotomy, with or without partial laryngectomy; (2) complete laryngectomy by the method adopted in Solis-Cohen's case; (3) complete laryngectomy in cases of extensive laryngeal

disease with glandular involvement. Examples of all three are beginning to multiply, to such an extent that it will not be long before we shall have a collection of details sufficient to afford a fairly positive knowledge of their real value, together with a fund of technical knowledge relating to the subject which cannot fail to be of material aid for future guidance.

1. Every malignant growth of the larynx of intrinsic origin which can be dealt with should be treated by an operation in the absence of a decided indication to the contrary, and the operation should be performed with the least possible delay.

2. Every tumor of the larynx suspected to be malignant, of intrinsic origin, of limited extent, and apparently within reach of free removal, justifies an exploratory thyrotomy in a suitable patient, in the absence of infiltration of the surrounding structures and of affection of the lymphatic glands.

The method of operating pursued by Butlin and Semon has been described in their published writings. It applies distinctly to cases in which the disease is absolutely confined to the interior of the larynx. Preliminary tracheotomy is done with the insertion of the tampon cannula and its careful adjustment. The anterior part of the thyroid cartilage is laid bare with scalpel and raspator; it is opened exactly in the median line, and the two sides of the larynx are held apart, preferably with two strands of strong silk inserted through the anterior parts of the lateral wings of the thyroid. After the latter has been split open, undue violence in holding the halves apart must be strictly avoided. At this stage it will generally be necessary to protect the parts from mucus and saliva by packing the lower part of the pharynx with a large aseptic sponge secured by a string and passed through the laryngeal wound upward. There are two recommendations upon which Semon lays special stress: (1) The surgeon should be provided with a forehead reflector and a good light, and as has already been suggested by the writer for deep operations in the pharynx, he should if possible have at hand a small two- to four-candle power electric lamp, to be used for the purpose of securing the best possible illumination of the interior of the larynx for the detection of every possible bit of diseased tissue. (2) Before he begins the removal of the growth the whole side of the larynx to be operated on should have applied to it a five-per-cent. solution of cocaine, for the pur-

pose of contracting the capillaries on that side and preventing parenchymatous bleeding, which otherwise is sure to interfere with and greatly prolong the removal of the growth proper, while at the same time it may allow suspicious portions to remain behind.

The importance of the two above mentioned measures is strongly insisted upon. The field of operation having been thus prepared, the diseased soft tissues are thoroughly removed to at least half an inch from the periphery of the growth, and if necessary the underlying cartilage is scraped or even removed, the base being firmly scraped with a sharp spoon. The use of the galvano-cautery will seldom be required. Every source of bleeding having been stopped, the whole interior of the wound is dusted with pulverized iodoform, or with iodoform and boric acid in equal parts, and the tampon cannula is immediately removed. The whole of the wound is then covered with cyanide or iodoform gauze.

In cases where the more extensive resection of the thyroid or even extirpation of one-half of the larynx is contemplated, the parts of cartilage to be removed should be freed from their perichondrium and from the surrounding soft parts by means of an elevator. In other respects the operation is the same, only more extensive than mere thyrotomy with removal of soft parts. It is generally not necessary to prophylactically ligate the laryngeal arteries. Where the epiglottis or the aryteno-epiglottidean folds are diseased, the best means of access to them is subhyoidean pharyngotomy.

For after-treatment, both Wagner and Butlin immediately remove the tampon cannula, and from that time use no tracheal cannula whatever; and the wound having been dressed, as above described, the patient is not propped up in bed, but is placed horizontally on the side corresponding to the half of the larynx operated on, with one small pillow under the head. Instead of plugging the wound with gauze as formerly, Mr. Butlin dusts it at least twice daily for the first few days with the antiseptic powder by means of a powder insufflator. The application can be made to the best advantage when the patient is swallowing, as during the act of deglutition the wound in the neck is separated sufficiently to admit the end of the powder-blower, so that the powder may be thrown directly against the raw surface, which should be thoroughly covered by it. The external covering of cyanide or iodoform gauze

should be removed as often as wet by secretion. Although nutrient enemata may be required for the first few days, the experiment may be tried on the day of the operation, or soon thereafter, of allowing the patient to attempt to drink a little water while leaning with the upper part of the body well over to the edge of the bed. In case of any impediment to the closure of the larynx during this act, the water will run directly out of the wound and no harm result. Should the experiment succeed, milk may at once be taken in the same way, and the necessity for rectal feeding be avoided. The external wound gradually closes by granulations, which may have to be stimulated by applications of nitrate of silver.

Turning now to the method of operation classified as No. 2, we find that a distinct advance has been made in the treatment of cases requiring complete extirpation. It was first proposed and practised by Prof. J. Solis-Cohen, of Philadelphia. The patient upon whom he originally employed it in 1892 is still living and well. In this operation, as in several similar to it, the larynx was completely removed and the severed ends of the trachea brought to the external edges of the cervical incision and there retained, communication between the lungs and the pharynx being thus totally and absolutely cut off. The great advantages of this plan over the usual methods are:

1. The danger to life from inspiration pneumonia is greatly lessened, owing to the shutting off of the mouth from the trachea.

2. Swallowing is accomplished with great ease and as freely as under ordinary circumstances.

3. In at least three cases thus operated upon, the power of phonation has been acquired with a voice fully as satisfactory as that produced by any artificial appliance, and without either the inconvenience and discomfort of an artificial larynx or the danger to the adjacent parts from the irritation of its presence. The mechanism by which phonation is accomplished in these extraordinary cases has not been explained. Cohen's patient is able to make his voice distinctly heard from one end to the other of the great hall of the New York Academy of Medicine.

4. The comfort of the patient is greatly increased, and the disfigurement of the other operation and the wearing of the artificial larynx largely done away with. It is entirely probable that under certain conditions this method will prove to be the most satisfactory

for complete laryngectomy of any yet proposed, and it is to be hoped that it may be given a sufficient trial to prove whether or not the cases already reported have been but a result of a happy accident rather than the first illustrations of a definite rule.

As to the third variety of operation, it has often been insisted that in order to insure success malignant disease of the larynx must be treated as early in its history as possible, and at least before involvement of the neighboring glands has taken place. Unfortunately, in the history of the past early operation has not always saved life, but on the other hand several eminently successful cases have been in patients who suffered from a tolerably extensive condition of disease. The management of cases of extensive laryngeal disease, therefore, becomes a matter not only of great importance but of lively interest, especially when it is remembered that perhaps a majority of patients are not seen by the specialist or surgeon until the disease has made considerable progress, and the time most favorable for operation has passed.

Several years ago operations were attempted upon such patients with only here and there an exception to the inevitably and immediately bad result. Subsequently they were generally left to their fate. Of late, under the influence of improved methods and increasing knowledge a hope—a small hope indeed, but worthy of all encouragement—has been aroused by the excellent work of several men. Prominent among these may be mentioned Mr. Watson Cheyne, of King's College Hospital, London, whose efforts in this direction are now attracting much attention, and who in his admirable Lettsomian Lectures (*Lancet*, Feb. 15 and 22, and March 14, 1896) upon "The Objects and Limits of Operations for Cancer," delivered before the Medical Society of London last February, says: "As compared with cancer in the breast, the disease in the throat is in some ways more favorable for cure; in other ways less so. Primary disease of the breast is by far the more favorable of the two, for there it is fully exposed to view, and there is plenty of room for its free removal without endangering important structures. In the mouth and throat, on the other hand, the disease is close to if not involving many important parts, the space in which one has to work is very limited, any considerable margin of healthy tissue cannot be obtained, and the early spread of the cancer to muscle tends to distribute it over considerable area. In the

throat, moreover, the disease is much less favorable for operation, because the septic elements come into play, and thus instead of having to do with an operation in the breast where the mortality is practically *nil*, we have to face very considerable risk of death from septic disease. On the other hand, cancer of the mouth and throat is more favorable as regards the glandular deposits, for in the neck we have an extensive glandular area exposed to view which can be much more thoroughly dealt with than in the case of the breast. It is true that many surgeons look on the glandular trouble as a most serious part of the disease. With this I do not agree. In another respect, cancer in the throat is more favorable than in the breast, namely, that in it metastatic deposits are infrequent."

As to the neighboring lymphatics, Cheyne believes that they should be removed as in cancer of the breast. It is seldom that no enlarged lymphatic glands can be felt in these cases, and usually they are of considerable size. Whether they can be felt or not, the lymphatic area should be cleansed out. Unless the lymphatic enlargement is very extensive or adherent to a variety of structures in the neck, and not merely to the sheaths of the vessels, the operation will be more thoroughly done and the patient will have a better chance of recovery and cure if enlarged glands are already present.

With regard to preliminary tracheotomy, Cheyne, agreeing with many other excellent authorities, does not believe in the insertion of the tube several days prior to the performance of the main operation. Personally, the author does not think his ground upon this question well taken, the objection being that in three or four days after the insertion of the tube there will be a collection of septic matter around it which may get into the trachea after the performance of the main operation. Such an accident could probably be avoided by extending the time between the two operations to ten days or more. It is desirable, however, that this question—namely, when preliminary tracheotomy should be performed—should receive more careful attention than has hitherto been accorded it, as it is without doubt an important factor in the patient's welfare.

These three varieties of operation just described may be said to finally represent the most recent additions to our present resources for the surgical relief of malignant disease of the larynx.

Turning now to the statistics of these and

similar operations performed upon the larynx, we find according to a recent valuable article published by Schmiegelow, of Copenhagen, in *Gougenheim's Annales* for April, 1897, that during the past six years the mortality resulting from extirpation of the larynx has been materially diminished. Thus up to 1880, according to Holmer, the mortality was forty-two per cent. Tauber reports a rate of sixty per cent. following total extirpation of the larynx between 1866 and 1890. Between 1880 and 1888 Schier found that the rate had fallen to thirty-four per cent. Since 1890, however, the reports are much more hopeful, for the same observer finds that the rate during that period has been reduced to twenty-two per cent. Schmiegelow, carrying the reports up to the present time, finds that the percentage of cures since 1890 has been 13.5 per cent., and of immediate mortality 18.7 per cent.

#### *FRACTURE OF THE PATELLA; AN ARTIFICIAL JOINT.*

Dr. A. M. PHELPS recently presented a patient to the Section on Surgery of the New York Academy of Medicine who had sustained a fracture of the patella the first week of last August. He went to St. Vincent's Hospital, and was treated there and discharged. In the second week of October he again fractured the patella, and was sent a week later to the City Hospital. When seen a few days later the limb was enormously swelled and the joint filled with fluid. The appearances were those of purulent effusion. Accordingly on November 7 Dr. Phelps operated on him. The case was presented because of the novel procedure adopted.

On opening the joint it was found that the synovial sac had been totally destroyed, that the cartilages of both the tibia and fibula had been almost entirely destroyed, and that complete excision seemed necessary. After he had succeeded in removing all of the diseased structures, the parts looked so much better that he resorted to a procedure used by him in two or three cases—*i.e.*, the endeavor to restore a normal joint by interposing some of the soft tissues between the ends of the bones, thus preventing the contact of bone with drainage. The patient was lost sight of for a time, but returned recently with the function of the joint preserved.

Dr. Phelps said that the reason he had resorted to this procedure in the present case

was that in operations for angular deformity of the hip he had succeeded in obtaining a very good artificial joint. Last fall he had adopted the same plan instead of amputation in a case of ankylosed finger. Two incisions had been made, one on either side of the finger, the bones divided, and then one portion was made convex and the other concave, so as to simulate the natural surfaces of a joint. The arterial supply having been left intact, he turned in the flaps of cellular tissue between the ends of the bones, and obtained an almost perfect result. He had also used this method in three cases of complete excision of the knee. In one done a year ago a fairly good motion had been secured; in another the result was bony ankylosis; and in a third case motion to an angle of about  $15^{\circ}$ .—*Medical Record*, Feb. 5, 1898.

#### SOME REMARKS ON RECTAL SURGERY.

An interesting paper appears on this subject in *The Lancet* of April 2, 1898, by THOMAS BRYANT. From a careful consideration of these cases of villous rectal growths the following conclusions seem to be reasonable:

That a villous growth of the large intestine is by no means uncommon, and particularly in women.

That when an adult is liable to attacks of abdominal straining, associated with the passage from the bowel of rice-watery mucoid fluid or thick mucus in any quantity, the suspicion of a villous growth should be excited.

When the straining is persistent, or relieved by only brief intervals, and the blood becomes mixed with the mucous discharge, the probabilities of a villous growth are much strengthened.

When prolapse of the bowels becomes constant, and this is attended with the discharge of bloody mucus or blood alone, careful search for a villous growth should be made.

The diagnosis becomes clear only when the growth appears with the prolapsed bowel at the anus or can be detected with the finger. In all cases of intussusception in adults the question of a villous or polypoid growth being the cause should be entertained.

#### A SUGGESTION FOR THE OPEN METHOD OF SUTURE OF OLD FRACTURES OF THE PATELLA.

BARKER contributes a valuable paper on the above subject to *The Lancet* of April 2, 1898.

The knee-joint is now so frequently opened both for injury and disease that all the details of the operation appear to the author to claim a very careful consideration. It is for this reason that he ventures to suggest a method of opening the joint where we propose to wire the patella for old fractures, which appears to him to offer many advantages over other methods commonly in use. Among these may be named the single vertical cut over the front of the patella, the H-shaped incision and the semilunar cut with the curve downwards as perhaps most in vogue. Each of these has often seemed to him to have certain disadvantages, the chief of which are, he thinks, as follows: The single median vertical incision doubtless gives free access to the fragments, but unless it is made very long the latter cannot be manipulated easily through it. It is, therefore, difficult to freshen the old cicatrized faces on both the upper and lower fragments either with saw or chisel. Moreover, in those cases intermediate between recent and very old fractures, where, say, a fortnight or three weeks after the accident we are called on to suture a broken patella, and where there is neither a fresh surface on the fragments nor as yet well organized fibrous tissue, but probably a quantity of half-organized blood and broken-down clot, we want more room for the removal of the latter and the cleansing of the cavity than we can secure through the vertical cut unless it be very long. But if it is extended the scar is in the line of pressure during kneeling and may be tender for an indefinite time. Besides this, the scar is less directly over the wire and may not bear the pressure of the latter without pain or even destruction of the skin. Finally, the cicatrix being in the middle line and probably for a long time at all events adherent to the parts beneath, there is less free play of the skin over the patella than there should be.

The H-shaped incision is not open to the first of these objections. It gives good access to all the parts involved both for wiring and removing blood, fibrous adhesions, etc., but the scar directly across the patella is as objectionable as that in its vertical axis in regard to adherence to the parts beneath and its relation to the wire, though it does not come so much in the way of kneeling. The semilunar cut with the curve across the ligamentum patellæ gives free access to the lower fragment, but not to the upper unless made very freely. The scar, too, lies in a position sure to be pressed upon in kneeling.

These several objections to the hitherto recognized methods of opening the knee-joint have frequently occurred to the author in former years, and have led him, in the last five or six cases in which he was called upon to suture the patella for old fracture, to adopt the practise now to be described, which he suggests is an improvement and which has certainly given him the best results, with much greater ease in operating than that found in the older methods. The aims of the procedure are to gain free access to the parts to be dealt with, with a minimum amount of cutting, and in such a way as to place the scar out of reach of pressure either from kneeling or from the knot of the wire; finally, to provide a good firm pad of tissue over the front of the patella and the uniting wire suture. The steps of the operation are as follows:

In the first place, the lower border of the upper fragment of the patella is made out by palpation as it is drawn down as far as possible by the thumb and fingers of the operator's left hand and steadied in the middle line of the limb. A curved incision is then made with its convexity upwards, beginning just below the level of the broken surface of the lower fragment, thence curving upward and crossing the middle of the upper fragment to end at a point on the opposite side of the joint corresponding with its point of origin. The tip of this flap is now dissected downwards to the broken surface of the upper fragment. The knife is then carried backwards across the face of the latter, clearing from it all fibrous tissue until the joint is open. Then the edge of the knife is turned forwards and placed on the posterior border of the broken surface of the lower fragment of the patella, and the fibrous tissue is similarly cleared from it. In this way all the fibrous matter previously uniting the fractured pieces is left attached to the deep surface of the middle of the flap and the remains of the patella bursa, but without disturbing the latter. The edges of the bone are then freshened with saw or chisel, the joint being protected meanwhile with a small sponge.

The author then passes the silver suture as follows: A stout-handled needle with an eye near the point (the same as that devised for his subcutaneous method of patellar suture) is thrust through the skin immediately under the lower border of the distal fragment. (The skin may be previously punctured with a knife.) It is then thrust through the liga-

mentum patellæ, scraping the border of the fragment in the middle line and passing behind both it and the upper fragment. When the point has reached the upper border of the latter it is made to pierce the attached muscles in the middle line of the fragment. Here it is threaded with stout silver wire and the needle is withdrawn, carrying, of course, the wire behind to the fragments; but when the point of the needle has cleared the lower edge of the lower fragment it is thrust in front of the latter under the flap until it can be unthreaded in the original wound. The wire now includes the broken fragments of the patella, the two free ends crossing in front of the gap between them. Each end of the wire is now threaded through a bar of steel twice, and with these bars in the hands a strong pull can be made upwards with the lower end and downwards with the upper, the latter being in the operator's right hand and nearest to him. By this strain the fractured surfaces are brought close together, aided by the fingers of an assistant. When it is seen that the adjustment is correct a few twists of the wire fasten the fragments securely. Then the wires are cut about half an inch from the twist and the ends are flattened down transversely. All clots should, of course, have been previously removed from the joint with a small sponge. The flap containing the skin, the remains of the bursa patellæ, and the fibrous material from between the fragments, is now laid down over the patella and forms a thick pad covering the wire. It is carefully stitched all round without any drainage, unless there is decided oozing, when each angle may be left without a stitch. But as a rule, if a soft elastic dressing is at once applied and firmly bandaged there is no accumulation of blood in the wound and no need for drains. No splint is required, and the patient is encouraged to gently move the joint in bed from the first; after the removal of the stitches on the tenth day he should be urged to do so. Besides this, massage should be employed daily all round the joint.

In the cases in which the author has employed this method primary union has been invariable, and the result has been more satisfactory than in those operated on by the other methods. In the author's first case—that of a powerful seaman—the strength of the bond of union between the fragment was so great that he returned to his calling and could do anything with the limb; and when about a year later he was put to

a great strain in heavy weather the opposite patella broke, but that with the wire round it still held firm. It might be objected to this method that the wire on the articular aspect of the patella would give trouble, but so far this has not been found to be the case; and, indeed, being perfectly smooth and more or less buried in the bone by the strain put upon it, this need hardly be expected. The saving of time effected by this method of throwing the wire round the fragments rather than by boring them is great. Moreover, to drill the bones exactly in the same places is very difficult, and the danger of splitting them in the process is not imaginary. Both these difficulties are overcome by the above method, which of necessity brings the fragments into the same plane and does not weaken them in the least.

The author would be very much interested, if other surgeons should adopt this method, to hear their opinion in regard to its merits. He has hesitated to dub it "a new method," being rather skeptical about anything nowadays being "new" in surgery. But so far his reading or observation has not brought any similar method to his knowledge. For recent fracture of the patella he sees no reason at present to depart from his method of subcutaneous suture, which he applies at once to every case he meets. This he has done between twenty and thirty times with good results, some of the cases having been already published.

---

*NOTES OF A CASE OF PERFORATING  
GASTRIC ULCER; OPERATION  
AND RECOVERY.*

The following case is reported by SHAW in the *British Medical Journal* of March 26, 1898:

Miss H., aged twenty, an assistant in a shop, had been suffering from gastric ulcer since September, 1896, and had at intervals been under medical treatment. On June 24, 1897, she was in the shop as usual, but was in great pain all day. Nevertheless her food on that day included rhubarb, strawberries, tomatoes, bread and butter, with tea. About 9 P.M., some four hours after tea, she suddenly felt acute pain in the stomach, rapidly spreading over the whole abdomen, but managed to walk home, a distance of two or three hundred yards, preferring that method to the jolting of a cab.

The author saw her at 11 P.M., when it was evident that perforation had occurred. The pulse was 120, the temperature 100°; liver

dulness was still present, and there was no distention. The belly was too tender to elicit the presence of fluid. Consent was only obtained for operation in the morning, so she was put under morphine, and dry heat applied. Next day her condition was much more grave, but at 9 A.M., with the help of Dr. Ryley and Mr. Blake, the author operated.

An incision above the umbilicus, in the middle line, was made four inches in extent, and immediately the peritoneum was opened signs of the lesion were evident. Gas and fluid escaped, and large flakes of lymph were found, especially between the stomach and liver. The stomach was somewhat contracted, but not empty, and when drawn into the wound the ulcer was easily detected on the anterior wall, near the pyloric end. The edges were thin, ragged, and undermined, without evident induration; there was no large aperture, and evidently some slight attempt at repair had taken place, although the gentlest handling caused more of the contents of the stomach to escape. The ulcer was closed by a double row of Lembert sutures, and to afford further security a portion of omentum was also fixed over the weak spot. The lymph was removed by careful sponging, an incision made below the umbilicus, and the abdomen washed out with hot boiled water. It was necessary to repeat the flushing several times, as on passing a glass drainage tube into Douglas's pouch vent was afforded to nearly a pint of purulent fluid. The abdomen was then closed, several gauze strips being left in the upper wound, taking care that one passed up under the liver, and others proceeding directly to the line of sutures. Just as the dressing was completed vomiting occurred, so the stomach was immediately thoroughly washed out. The operation lasted an hour and a half, and was well borne, her condition being rather better than at the beginning.

The after-progress was uneventful. For two days she was very ill, but then commenced to improve. After the first day sips of hot water were given, and at the end of forty-eight hours small quantities of champagne and milk alternately were administered. Vomiting occurred once on the third day. During this time drainage, especially from the tube in Douglas's pouch, was very free. The gauze strips were removed on the third day, but the lower wound was drained for a week. At the end of a fortnight both wounds were soundly healed. The temperature at no time rose above 102°

F., and was normal in ten days. Menstruation, which for some months had been in abeyance, occurred on the third day after operation, and has since been regular. The patient was allowed up in the third week, and solid food gradually given. She has now (February 24) been at work for some months, and, excepting when indiscreet in diet, there is practically no pain.

The points of interest in this case seem to the author to be:

1. The ragged, undermined character of the ulcer, without induration or any large perforation.
2. The time after perforation (twelve hours) that the operation was successfully undertaken.
3. The necessity for thorough flushing and drainage, especially through Douglas's pouch.
4. The fact that such an operation could be satisfactorily and successfully performed in a small room of an ordinary lodging-house, at very short notice, and without skilled nursing being obtained either at the time of or subsequent to the operation.

## Reviews.

---

THE GENESIS AND DISSOLUTION OF THE FACULTY OF SPEECH. A Clinical and Psychological Study of Aphasia. By Joseph Collins, M.D.  
New York: Macmillan & Company, 1898.

This octavo volume of nearly 450 pages embodies the monograph of the author to which was awarded the Alvarenga prize of the College of Physicians of Philadelphia in 1897. The author's prefatory note denotes scientific accuracy, even if it does not show great business foresight, for he tells us that since the MS. left his hands in April, 1897, several important contributions have been made to our knowledge of aphasia, but that he has not had the time or opportunity to give them the consideration and discussion that they merit. Naturally this gives one a feeling of disappointment that he is not obtaining the best modern summary of the subject, but a careful examination of his pages shows that while complete studies of these new subjects have not been made, a sufficient number of verbal changes have been introduced by the author as he read the proofs to make the volume as worthy to-day of the prize which was awarded to it a year ago as ever. It is emphatically a creditable production to the author and to the American profession, and is written in an

interesting, consecutive way which leads one from page to page with interest.

The volume consists of twelve chapters and two appendices. The first chapter deals with disorders of intellectual expression; the second with the history of aphasia; and then follows others upon the analysis of the genesis and function of speech, the conception of aphasia, the various forms of aphasia and its diagnosis, causation, morbid anatomy, and treatment, the final chapter dealing with the medico-legal aspects of aphasia. Appendix 1 deals with confusional aphasia and Appendix 2 with articulatory kinesthetic aphasia. A noteworthy part of the book is the copious and apparently accurately prepared foot-notes which indorse many of the statements made in the text. As a complete story of our knowledge of this interesting condition Dr. Collins' book deserves all praise.

ATLAS AND ESSENTIALS OF PATHOLOGICAL ANATOMY. By Dr. O. Bollinger. Volume II: The Urinary Apparatus, Sexual Organs, Nervous System and Bones. With Colored Figures and Plates. Price, \$3.00.  
New York: William Wood & Company, 1898.

The first volume of this Atlas we noticed with much pleasure and praise in the May issue of the GAZETTE. The present Atlas deals with equally interesting topics, is equally well executed, and exceedingly valuable, so that we can cordially commend both the text and the plates.

ACCIDENT AND INJURY: THEIR RELATIONS TO DISEASES OF THE NERVOUS SYSTEM. By Pearce Bailey, A.M., M.D.  
New York: D. Appleton & Company, 1898.

We confess that we picked up this book with considerable curiosity born of the desire to know what field its author intended to cover, and we learn from the preface that his object has been to furnish a systematic description of the nervous affections which result from injury and fright and which are usually classed under the familiar term of the traumatic neuroses. The introduction consists in a discussion of the previous history of the patient and history of the accident, physical evidence of predisposition to nervous diseases, and a consideration of the examination as to actual injury. The rest of the book is divided into four parts. The first deals with organic effects of injury to the nervous system, the second with functional effects, the third with malingering, and the fourth with the treatment of traumatic neuroses, the volume closing with an index of names and an index of subjects. This

method of making an index of names is too infrequently resorted to in this country and is one of the valuable characteristics of foreign medical books. The volume is illustrated by no less than fifty-five black and white illustrations, many of which are taken from other authors, although quite a large number are entirely original. The book is evidently the result of a good deal of personal experience and contact with the class of patients described in its pages. Indeed, a peculiarity of these pages is the frequent insertion of accounts of cases with which the author illustrates his text. Most of the chapters are also finished by a fairly complete bibliography of the subject of which they treat. Only when the author goes far afield for his illustrations, as on page 314, do they prove worthless as additions to the volume. Amongst the various books which come to the editorial office of the *GAZETTE* this is one of those which is put aside for careful study, with the thought that much can be learned from it.

A TEXT-BOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By John J. Reese, M.D. Fifth Edition, revised by Henry Leffman, A.M., M.D., Ph.D. Philadelphia: P. Blakiston, Son & Company, 1898.

Old students of the University of Pennsylvania will remember that the author of this book had an elegance of diction and a clearness of expression which surrounded his lectures with a pleasing atmosphere over and above that connected with them by reason of their innate importance. Since Dr. Reese's death the difficult task of editing subsequent editions in such a way as to maintain the usefulness of this book has fallen to the hands of Dr. Leffman, who is well known as the pathological chemist to the Jefferson College Hospital and for the notable chemical analyses which he makes from time to time.

In the present edition we are told that very little has been added to the general principles of the subject, and that the new matter consists largely of reports of peculiar or difficult cases. The book is written chiefly with the idea that it will be of value to the medical man rather than to the lawyer, and it is not a laboratory manual nor a comprehensive work for experts, but a student's text-book and reference work for practitioners. The book is exceedingly well printed, on good paper with large type, heavily leaded, and is a credit to medical jurisprudence on this side of the water. That part of the book devoted to the consideration of poisoning and drugs seems to us of unusual merit.

## Correspondence.

### LONDON LETTER.

BY RAYMOND CRAWFORD, M.A. OXON., M.D., M.R.C.P. LOND.

The various medical societies are now shutting up shop for the summer—if we may dignify by that name the hyperborean climate in which we are struggling to exist; nor is there much of note to record from other medical sources. Last month Mayo Robson read a very valuable and instructive paper before the Leeds and West Riding Medico-Chirurgical Society on a "Method of Exposing and Operating on the Kidney without Division of Muscles, Vessels, or Nerves." We fancy that this method has been practised also in New York. Mayo Robson describes his procedure as follows: Starting from the inner side of the anterior superior spine of the ileum, the incision is carried back in a slanting direction towards the tip of the last rib. The fibers of the external oblique muscle and of its aponeurosis are split and retracted, so as to expose the internal oblique: this muscle is similarly split in a line between the ninth costal cartilage and the posterior superior iliac spine. The fibers of the transversalis can be dealt with along with those of the internal oblique. On retracting these muscles, the transversalis fascia is seen lying at the bottom of the lozenge-shaped aperture; this is incised, and the kidney exposed lying in the perirenal capsule of fat. The fingers will then readily work their way to the kidney itself, which can be grasped and freely manipulated by temporarily removing the retractors. In many cases the kidney can be brought clear out of the wound and explored. Mayo Robson detailed a number of cases in which a calculus was thus extracted and the wound sutured before returning the kidney into the abdomen. He claims many advantages for this method. First and foremost there is no weakening of the abdominal wall because the muscle fibers are not cut; also no vessels are cut, so that healing by first intention is favored. The absence of hemorrhage also means saving of time and diminution of shock from the operation. As no nerves are divided, there is no fear of paralysis of the rectus and other muscles. The operation is performed with the patient lying on his back, which, besides being much more convenient to the surgeon and anesthetist, saves a deal

of disturbance of the patient. The duration of convalescence is materially shortened; the patient can safely be allowed to sit up at the end of the second week, as there is no fear of the wound giving way. Lastly, in view of the frequent difficulty of diagnosis in renal surgery, it is satisfactory to have a method of exploration that involves next to no risk to the patient.

Mr. Mansell Moullin's paper on the "Treatment of Tuberculous Disease of the Bladder" gave rise to an interesting discussion at the Clinical Society. It cannot be said that at present either medicine or surgery is equipped with any adequate means of combating the condition. The various medical remedies are at least innocuous, but the same can hardly be said of the attempts of surgery to treat the disease by local applications. In the first place the bacilli are buried far too deeply to be affected by remedies, which at best can only touch the surface; and in the second place there is the danger of introducing septic organisms into the bladder. Mansell Moullin was in favor of early suprapubic cystotomy with a view to erosion or excision of the disease. One great objection to any operation in our mind lies in the fact that tuberculous cystitis is practically always secondary to tuberculosis elsewhere, usually in the genito-urinary tract, and most often in the epididymis or vesiculæ seminales. Another objection to operative interference is that tuberculosis of the bladder is nearly always latent, and gives no symptoms until the disease is too far advanced for removal; and even in advanced cases the examination of the urine more often than not gives a negative result. Mr. Freyer said that he had opened the bladder six times for tuberculous cystitis and had regretted it in every case but one, as the local mischief seemed to increase after the erosion, and the healing of the suprapubic wound habitually ran an indolent course. Over and above this, suprapubic cystotomy is not a measure to be lightly taken in hand.

The indefatigable editor of the *Practitioner*, Mr. Malcolm Morris, has sought to emulate his Jubilee number of last June by a similar June number this year devoted to the question of Tuberculosis in all its manifold medical aspects. The venture is in every way a great success, and the best thanks of the medical profession and of the community are due to the editor. The articles are contributed by a very select staff of writers, and will certainly be widely studied. In the out-

patient practise of a metropolitan hospital one is constantly reminded of the frequency of the disease, and of one's utter inability to grapple with it. Yet one was hardly prepared to read that at least one-eleventh of the whole population of these islands dies of consumption alone. The post-mortem room, too, reminds one of how large a percentage carry some tubercular scar to their grave, though there may have been no suspicion of tubercular taint in their lifetime. To therapeutists the remarks by Sir Samuel Wilks and Dr. Hector Mackenzie in their respective contributions will be full of interest. Sir Samuel Wilks, from the experience of a lifetime, has come to believe very little in drugs even as adjuvants to Nature's great remedy, fresh air. Dr. Mackenzie says all that there is to be said for the few drugs on which we principally rely—cod-liver oil, creosote, and guaiacol. In skilled hands no doubt all of these are at times effective, but one sometimes doubts whether their stock use in hospital and dispensary practise is not productive of a balance of harm. However, something will have been gained if by their manifest inactivity they serve to clear the field for preventive treatment on the one hand, and for the establishment of suitable sanatoria on the other, within the reach of the destitute many as well as of the well-to-do few.

---

#### PARIS LETTER.

---

BY A. R. TURNER, M.D. (PARIS).

---

The only event of any importance recently has been the Blanchard-Heim scandal. During the lifetime of Dr. Baillon, Professor of Natural History at the Faculty of Medicine of Paris, the assistant professor was Dr. Raphael Blanchard, son of the well known biologist of that name. A more recently appointed assistant professor was Dr. Heim, who likewise held the appointment of superintendent of the Laboratory of Natural History, in which medical students worked. Some time after Dr. Baillon's death, Dr. Blanchard was appointed professor of natural history and relieved Dr. Heim from the post the latter had held, taking charge of the Laboratory himself. He accused Dr. Heim of having misappropriated—in one word, stolen—microscopes and objects of value belonging to the Laboratory. The case was tried before a meeting of the Council of the

University, and though the result did not seem very definite, Dr. Heim was placed on the retired list. Dr. Heim has strongly protested in various ways against what he has termed a persecution due to personal enmity between himself and Dr. Blanchard. As the latter was previously unpopular with the medical students on account of supposed severity in examinations, and from the fact that he delayed for a considerable space of time the publishing of the second part of a work on Natural History, which the purchaser was compelled to pay for when buying the first part, the medical students did not neglect this opportunity of taking part against Dr. Blanchard, and thus relieving their feelings by a little noise. Accordingly when Dr. Blanchard undertook to deliver a course of lectures as professor of natural history, he was greeted with such howls and other marks of disapprobation that he was compelled to stop speaking, nor has it been possible for him to continue, notwithstanding the appeals and threats of the Dean of the Faculty himself. I may add that one is surprised to find in many instances how weak the power of discipline seems to be in the French faculties, above all when compared with what seems the unjust severity displayed on many occasions in the French secondary schools.

At a recent meeting of the Academy of Medicine Professor Dieulafoy described a case of syphilis of the stomach, in which the affection had shown itself with the symptoms of gastric ulcer. A recovery was readily obtained by an antisyphilitic treatment. Professor Dieulafoy stated that such observations were not frequent, and concluded by saying that they would be met with more frequently if thought of. They may assume the various forms of simple hemorrhagic erosions, of gummatous infiltration of the submucous coat, of circumscribed gummata, and of ulcerations and cicatrices of gummatous ulcerations. Dr. Dieulafoy looked upon the gastric juice as playing a certain part in the affection, by its action upon the ulceration, which it tends to irritate and enlarge. As the symptoms were identical with those of simple ulcer of the stomach, it was only by a past history of syphilis and the efficacy of an antisyphilitic treatment that a correct diagnosis could be made.

At the same meeting Professor Huchard, who has written several works on heart disease, and who is likewise known for his chauvinism, communicated a report by Dr. Combemale on the use of thallium acetate in

the night sweats of tuberculous patients. It should be used with caution, as it may cause pains in the legs and complete alopecia.

At the Congress of Internal Medicine, held last April at Montpellier, some remarks were made by Drs. Ducamp, Sabatier and Petit which would tend to show that enteric fever cannot be caused by eating oysters coming from waters infected by the germs of that disease. From bacteriological researches made at Cette, a port on the southern coast of France, it would seem that neither the bacillus coli communis nor the enteric fever microbe were to be found in the oysters of the region, even when placed near the opening of a drain for an entire month, and that even after inoculation with Eberth's microbe, the latter soon disappeared, either from the action of the salt water, or because of the oyster's resistance.

Dr. Netter, assistant professor at the Faculty of Medicine of Paris, has drawn the attention of medical practitioners to the presence in Paris of a slight epidemic of cerebro-spinal meningitis. He reports five cases with autopsy observed at the Trousseau Hospital for Children. Drs. Siredey, Delpeuch and Fernet have likewise reported some cases occurring among adults. The differential diagnosis is frequently difficult, and in some cases it may be necessary to tap the lumbar region of the cord and to obtain the meningococcus from the fluid drawn.

In connection with this epidemic in Paris we may mention a similar epidemic observed at Athens by Professor Delyannis. This affection has so far occurred every year in the country around Athens, and during the past year some sixteen cases were observed from November to January. Professor Delyannis' *chef de clinique*, Dr. Assimis, recently gave a description of the disease in the *Presse Médicale*, as well as a report on the microbes discovered. Six cases were fatal, and two autopsies were performed. In most of the cases a frequent and characteristic condition was coma; albuminuria and labial herpes were likewise observed. Though in some cases the malady was not very severe, consciousness persisting throughout, in others the usual severe symptoms were observed.

The results of the two autopsies were as follows: Concurrently with the various signs of congestion found in most cases there was present a seropurulent exudation on the convex surface of the brain below the arachnoid, as well as on the under surface. On the

under surface of the cerebellum pseudo-membranous deposits were present. The coccus found in the pus did *not* resemble that of pneumonia, in that it was not pathogenic for the mouse.

Dr. Marfan, one of the most eminent of the French physicians devoting themselves solely to children's diseases, recommends the following methods of administering some of the drugs used in whooping-cough. Against the fits of coughing belladonna should be given as follows:

Syrup of belladonna (Fr. Ph.), 25 grammes;  
Syrup of tolu (Fr. Ph.), 100 grammes.

For children under two years, one to two teaspoonfuls daily; for children from two to three years of age, four teaspoonfuls daily; and for children from five to six years old, six teaspoonfuls. Give the above doses to begin with, and increase the dose regularly by one-half teaspoonful daily, until the fits of coughing diminish or at least there be signs of intolerance, such as dilatation of the pupils, dryness of the throat, redness of the cheeks.

Dr. Marfan considers the above drug to be most useful in some cases, but as necessitating care in its use. He considers antipyrin to be more easily employed in children, and recommends the following formula:

Antipyrin, 3 grammes;  
Syrup of orange flowers, 20 grammes;  
Distilled water, 100 grammes.

One teaspoonful of the above mixture contains ten centigrammes of antipyrin. Under two years twenty centigrammes may be given; from two to five years, fifty centigrammes; and from six to ten years, one gramme. The maximum doses should be respectively *one*, *two* and *three* grammes. Each daily dose should be given in three parts, at regular intervals.

Antipyrin should *not* be used when there is danger of catarrhal pneumonia, on account of its depressing effect.

Bromoform would seem to be a good preparation, and may be used in the following manner:

Bromoform, 7 grammes;  
Sweet almond oil, 30 grammes;  
Gum acacia, 30 grammes;  
Syrup of orange flowers, 40 grammes;  
Cherry-laurel water (Fr. Ph.), 10 grammes;  
Distilled water, q. s. to 300 Cc.

The initial doses are as follows: Children under six months, two to three drops; children from six months to a year, three to four drops; children two years old, eight drops; children three years old, twelve drops; six-

teen drops at four, and twenty to thirty drops after five years. A daily increase should be made of from two to three drops, and this is absolutely necessary in order to obtain favorable results.

Bronchial infection should be prevented by antiseptic precautions, such as washing out of the mouth, antiseptics of the nose, treatment of all lip sores and forms of rhinitis.

#### BERLIN LETTER.

BY JAMES J. WALSH, PH.D., M.D.

A noteworthy contribution to the literature of appendicitis is the article on the subject in the third part of Nothnagel's Diseases of the Intestine and Peritoneum, which has just appeared as a volume of the system of Special Pathology and Therapy, of which the great Vienna clinician is editor. For views as to appendicitis are quite as widely divergent over here in Europe—let us rather say more so—as in America. Its treatment is a point on which surgeons and physicians agree to differ even more than across the ocean.

On my way up from the German Congress for Internal Medicine at Wiesbaden, I stopped off at Jena, and heard a medical clinic and a surgical clinic on appendicitis. Professor Stintzing, the director of the medical clinic, is the editor, with Professor Penzoldt of Erlangen, of a System of Therapeutics that, despite its four-volume size, has reached a second edition in two years. He is known as a most conservative but a most successful therapist. He was just passing around the stool of a case of appendicitis that had been under treatment for twelve days in the wards under opiates. It was the first stool the patient had had since his admission, and Professor Stintzing said that he did not feel the least alarm if patients on the strictly limited diet required in these cases should not have a stool for fourteen or fifteen days. There was very little accumulation of fecal matter, and the thing above all to be avoided was the disturbance of Nature's protective adhesions by any increase of peristalsis. He scouted the idea that a purgative or salines should ever be prescribed in appendiceal cases. He considered it an utter misapprehension of the indications to employ them, and the statistics of the comparative mortality and morbidity of cases in which constipation or diarrhea had been present he could only stigmatize as one of those misapplied coinci-

dences of figures which have always worked so much harm in medicine, especially in therapeutics. As to the claim that appendicitis was a surgical disease, he considered it a specialist's pretension, and as such always sure to be exaggerated, especially when the significance of an ailment is first brought into prominence. The great majority of the cases, he thinks, run a benignant course and get well under purely medical treatment.

Across the hospital yard Professor Riedel, the director of the surgical clinic, could only say that all appendicitis, and all acute affections of the right iliac fossa, are surgical cases. The symptoms of acute inflammation to his mind always pointed to the existence of pus, and where pus was present the medical man must give place to the surgeon. He showed three cases of recurring appendicitis in which so-called medical cures had been effective in previous attacks; in all three operation disclosed the presence of walled-off abscesses, in one in fact of multiple foci of purulent inflammation, micro-organisms having found their way along the lymph paths and blood-vessels of the mesentery to infect distant parts of the peritoneum. There was a wonderfully homelike feeling created by this difference of opinion. It would be strikingly familiar, I think, to any American fresh from the benches of the medical societies at home.

Nothnagel's views, then, in the work which is supposed to sum up European medical opinion at the end of the century, are of special interest. His conclusions are practically a medical capitulation all along the line. For the terms typhlitis, paratyphlitis, etc., he finds scarcely any *raison d'être*. Inflammatory affections of the right iliac fossa are practically always due primarily to the appendix. His fine etymological sense (any one who has heard his clinics could scarcely help being struck by his easy, wonderfully simple and sympathetic style) will not permit him to accept the word appendicitis. To replace it he suggests "skolikoiditis." He considers that the primary stercoral typhlitis of the older authors is extremely exceptional. The acute symptoms of skolikoiditis he thinks with Sahle point nearly always to inflammation so acute that it probably is or will be purulent. A surgical consultant is practically always to be called. Eighty per cent. of the cases will get better on medical treatment, but since the etiological importance of a collection of feces in the cæcum as the origin of the disease is no

longer to be admitted, not purgatives but opiates must be given. He prefers, and this is a special remark made by many prominent clinicians over here when they suggest opium, the extract of the drug to any of the alkaloids, and especially to morphine. Nothnagel thinks that there need be no uneasiness if the patient should not have a stool for six to eight days.

Two interesting questions are touched upon—the family tendency to appendicitis, which has now been noted so often that it is generally admitted, and the question of the possibility of epidemics of appendicitis, two of which have so far been reported. The article is a masterly study of the interesting question, on which American workers have contributed more than any others, to make the present position of general medical opinion.

Professor Heubner gave the other day the practical results of some experiments on the therapeutic influence of phosphorus in rickets, which have been conducted in his clinic. The division of opinion in various pediatric clinics of Europe as to the value of phosphorus in the disease is most striking. The last two prominent writers on the subject—Comby and Hagenbach—hold exactly opposite views. The one finds it useless, the other a specific. Phosphorus fed to animals produces an increased bone formation, and if enough lime salts are not furnished in the food, then what would be new formed bone is only cartilaginous matter. Existent bone becomes denser. Rachitis does not, however, merely produce defective bone formation; it, like phosphorus itself, sometimes produces an excess of bone, or in defect of lime salts an excess of cartilage. There are, however, a series of rachitic bone lesions that are the expression of defective bone-making and are represented by an osteoporosis of the skeleton. These forms are much more common in certain parts of the country than in others. For instance, the descriptions of pathologists in Vienna and in certain parts of Southern Germany show that osteoporosis is a very common lesion. In these parts naturally phosphorus enjoys the reputation of a specific. Except in these cases, however, it is only as a tonic alterative that phosphorus does any good, and its results are only satisfactory in a small proportion of the cases. It seems possible, however, by knowing the ordinary bone lesions of rickets in a district, to be able to tell whether phosphorus will be of benefit or not.

A very interesting attempted application of phagocytosis to surgery is the effort to "fight pus with pus," that is being tried in a number of places in Germany now. Non-micro-organismal pus, that produced by the chemotactic influence of turpentine for instance, is called into action around a focus of chronic inflammation, with the result, so observers claim, that the active phagocytes put an end to the chronic inflammatory process, by consumption of the bacteria and their products. It is even claimed that the action of many so-called antiseptics lies not in their bactericidal qualities, but in their irritation, calling to the spot white blood-corpuscles that act as phagocytes.

---

ROME LETTER.

BY DILLON CARBERRY, M.D.

Within the past month the security of foreign medical men practising in Italy has been assured. A letter to Lord Salisbury from Sir Clare Ford, the British ambassador here, indicates that the agitation is at an end, and that no steps will be taken by the Italian Government to alter the existing laws in regard to foreign practitioners. This conclusion to what seemed, at one time, a serious crusade against the foreigners, cannot but be gratifying to them, while it is not considered unjust by the more liberal of our Italian *confrères*.

Dr. Pietro Pagello, who died lately in his ninety-first year at Belluno, was a curious example of the capricious dealings of fame. It may be remembered that it was he who treated Alfred de Musset at Venice for what the poet in his diary calls cerebral fever; for the skill of the Doctor in curing this anomalous ailment the recovery of his patient must vouch; but it was his romantic liaison with Georges Sand (which led to her rupture with de Musset) that placed him in the niche of notoriety.

Another recent death, that of the Honorable Cavallotti, though no less suggestive of romance, from its connection with that curious medieval survival the duel, has points of interest for the surgeon or the medical jurist. The conditions of the encounter, based on medical knowledge, were unusually severe; the wrist and forearm of each combatant being protected by tough leather gauntlets, so as to prevent the possibility of a mere wounded radial or severed tendons from causing a cessation of the fight. The swords

are always sterilized by the surgeons in charge, and should one of the duelists drop his point so as to touch the ground the fight is stopped until the point has been freshly antiseptized. The wound that killed Cavallotti was punctured and incised, as the swords were double-edged and pointed, making a most severe wound. The sword point entered the mouth through a gap left by the absence of three teeth; it sliced the tongue, divided the epiglottis, and opened the internal carotid. In an incredibly short time Montenovesi, the surgeon, succeeded in tying the left common carotid; but Cavallotti died within five minutes of the giving of the blow, curiously enough from asphyxia, due partly to spasm of the glottis, partly to escape of blood into the air-passages.

The Italian law punishes the duelist in proportion to the extent of the wounds inflicted; thus a wound that takes ten days to heal will condemn the giver to three months' imprisonment, while six months is the lot of one who inflicts a wound that refuses to heal in less than twenty days. Homicide is comparatively cheap; it costs five years.

The new antipneumonic serum of Pane comes in for a good deal of attention in these days, as very encouraging results are reported from Naples, where its use is warmly advocated by De Renzi. The value of the serum is undergoing active investigation in the Roman hospitals, and many authorities speak favorably of its action. In the medical section of the Policlinico Professor De Renzi, who has been the first to use the new serum, publishes a series of observations. The antipneumonic serum, he tells us, is prepared by immunizing asses and cows with very large doses of a most virulent culture of the pneumococcus. The injections of the serum are always followed by a marked fall in the temperature, pulse, and respirations. Although the general condition of the patient is much improved, the local lesions do not heal in any shorter period. Out of thirty-three patients treated, three only died; whilst the mortality amongst other patients reached twenty-four per cent. It is fair to note that only grave cases were selected for treatment where clinical instinct suggested an unfavorable prognosis.

De Renzi does not consider the action of the toxins to be very evident in the clinical picture of pneumonia, although he cannot deny their existence; he is persuaded that the toxic effects are not due to the direct

action of the virus. His opinions are founded on an observation of splenic tumors and hepatic swelling as not infrequent though not constant phenomena in the disease, and on the fact that the diplococcus in pure culture does not produce a very appreciable quantity of toxins. A careful observation of the blood-pressure in many cases has led him to believe that the process in pneumonia is sthenic before and asthenic after the occurrence of the crisis. He concludes by prognosticating that the serum must prove useful in treating the various manifestations of the action of the diplococcus, such as meningitis, pleuritis, and suppurative arthritis; but he thinks unfavorably of preventive inoculations owing to the short duration of the immunity conferred.

At a late meeting of the Associazione dei Medici e Naturalisti in Naples, Professor Pane added something to our knowledge of the morphology of Fraenkl's coccus. He has observed that the capsule of the coccus becomes more apparent as the disease advances; it is not seen in the cocci found in the spleen of infected animals killed during the first two days; it is well marked where the germs have been cultivated in the anti-pneumonic serum. For these reasons he believes that the appearance of the capsule represents a phenomenon of degeneration.

The whole question of the Pane-De Renzi serum was discussed at the last meeting of the Società Lancisiana degli Ospedali di Roma. Dr. Stefanucci-Ala's opinion was unfavorable; he doubted whether it was possible to provide a curative serum for pneumonia. Several distinct germs, that of influenza, to wit, the pneumococcus, the pneumo-bacillus, as well as other germs, were capable of producing pneumonia. Could the serum be active against each and every one of these? The non-acquirement of immunity by a previous attack militated against the presumed value of the serum. His observations, limited to three cases, of which one died and the others recovered, were not satisfactory, as the action of the serum was not marked. To this Stagnitta replied that while he agreed with Stefanucci, that many dissimilar germs, such as the pneumo-bacillus of Fraenkl and Frobenius, the bacillus of Eberth, that of Pfeiffer, and even a mold such as the aspergillus, were all capable of causing a croupous infection of the lung, with all the characteristics of genuine pneumonia, still at least ninety per cent. of the cases of croupous pneumonia proper must be at-

tributed to the action of the diplococcus lanceolatus of Fraenkl; it was to these cases alone that the new serum was applicable. As regards immunity he, agreeing with Silva and the Klemperers, was assured that what was expected from a serum was not so much immunizing as antitoxic properties; these the serum undoubtedly had. Dr. Gamba recorded four successful cases, and Concetti two unsuccessful. Several others spoke, the sympathy of the assembly being in favor of the use of the new serum.

In the current number of the *Supplemento al Policlinico* Sanarelli, the discoverer of the bacterium icteroides, publishes a review of his first experiments with his curative serum for yellow fever. The preparation of the serum differs somewhat from that of the more common antitoxins in this particular, that it occupies a much longer time on account of the exceptional difficulty which animals have in tolerating large doses of the virus; with a continuous intensive treatment in the horse it takes from twelve to fourteen months to procure a serum of sufficient strength. So far Sanarelli has been unable to discover any antitoxin in the blood of the immunized animals; his serum is a germicide, not an antitoxin; to be of service it must be used promptly. Sanarelli disagrees with Sternberg in the theory that the intestinal tract is the seat of the bacteria, and concludes that anuria, or diminished renal secretion, with albuminuria is much more typical of fatal cases than hemorrhages or black vomit. Finally, any curative efforts are in vain when symptoms of uremia are present.

The first experiments on eight patients proved these contentions; four, who were already anuric, died, the others recovered. The next series of observations was compiled at San Carlos do Pinhal, in Brazil, where a violent epidemic was raging. The serum used was that of a horse, and its intrinsic harmlessness was demonstrated in the person of the discoverer, who injected large doses, as a preventive, into his own body without suffering any unpleasant consequences. Of eight cases treated by subcutaneous small doses repeated, two died. It was then decided to practise intravenous injection of large doses, the "intensive" method; of fourteen patients so treated, four died. In all, out of twenty-two cases six only were lost.

Sanarelli is unwilling to deduce a statistic from these figures, but he draws attention to

the fact that the prevailing epidemic was of the severest type, with a mortality of over eighty per cent.; that all the cases treated were of a typical and severe nature; and that the presence of the bacillus icteroides was often demonstrated in the blood of patients during the course of the experiments. The preventive value of the serum was demonstrated in the case of the prison at San Carlos, where four cases of yellow fever had followed in rapid succession. The hygienic surroundings were *nil*, the inmates occupying one common chamber. No further cases were reported after the vaccination, although the fever continued to devastate the surrounding district.

A great deal has been already written about renal lesions in malarial infection, yet a recent memoir published in the medical section of the Policlinico by Rem-Pecchi, professor of medical pathology in the University of Rome, brings a certain amount of new material into the literature of this subject. Taking his position at the point indicated by Thayer and Hewetson (*Johns Hopkins Hosp. Rep.*, vol. v, 1895), he continues his observations—extended over many years—and deduces the following conclusions: (1) Malarial infection is capable of producing true renal lesions, but the number of such cases is small; in Rome, the complication is more prevalent amongst the young, and during the autumn. (2) All forms of acute and chronic renal disease, save the contracted kidney, may be produced by malarial poisoning; the attack is light as a rule, and of the catarrhal, desquamative or tubular type; it is readily cured, but if neglected may easily decline into a chronic form. (3) The renal lesion may appear during an attack or after; the post-malarial onset has a special significance to the physician, who must bear in mind the possibility of the occurrence of nephritis after the cessation of the fever. (4) The causation of these lesions is to be attributed to the irritation consequent upon the elimination of toxic elements and not to the plasmodium which, according to Baccelli, is pyrogenetic, not pyogenic.

The treatment advised by Rem-Pecchi is based on the free use of quinine, where the fever is active. He recommends a combination called Baccelli's mixture; it consists of sulphate of quinine, tartrate of iron and potash, arsenous acid, and water. Hemoglobinuria, he admits, may be one of the concomitants of cinchonism—never hematuria nor albuminuria. Bleeding from the

dorsal veins of the foot, as advocated by Baccelli, is very useful in the hemorrhagic and other acute forms.

Professor Rem-Pecchi quotes the history of the subject *in extenso* and gives the notes of over thirty cases.

The use of phenic acid in cases of tetanus, devised by Baccelli some years ago, has many upholders here. Dr. Ascoli, at a late meeting of the Royal Academy of Medicine, made an astonishing comparison between the relative values of the serum of Behring and Tizzoni, and the cure by phenic acid. The cases so far reported give the following results:

Treatment by Tizzoni's serum, died, 8 in 40.

Treatment by No. 1 Behring serum, died, 4 in 40.

Treatment by No. 2 Behring serum, died, 2 in 9.

Treatment by phenic acid, died, 1 in 30.

Leaving a considerable balance in favor of the carbolic treatment. There is a great tolerance for the drug in tetanus, and the use of large doses is indicated. For injection subcutaneously a three-per-cent. solution is used; the dose varies from one-half to ten grains; the maximum dose for the twenty-four hours seems to be forty-five grains. Local baths may also be used with advantage.

It is a pleasure to learn that during the terrible days of the Milan riots the medical profession was not found wanting at its post; and great praise is given by all to the heroism of the civil and military surgeons, who took an active part in tending the dying and wounded. The Ospedale Maggiore, where the greatest number of the wounded lay, bore the brunt of the work. In spite of this Professor Porro, of that hospital, was mobbed at the gates; but he turned upon the crowd, faced the shouting rabble, and compelled them to give way by the mere influence of his personal courage and determination. The hospital was guarded by the military subsequently. No official report has appeared as to the number of dead and wounded; the former may be over 200 and the latter possibly near 1000.

One of the most ghastly scenes in the riots occurred near Bari. Here Dr. Brandi, the poor-law officer of the district, was assaulted by the mob, chased into his house, and subsequently torn limb from limb (*sic*) by the villains, in the presence of his wife, who was dying from heart disease. His house was then burnt to the ground, the poor lady being carried into a cellar adjacent, where she shortly afterwards expired.

### THE TREATMENT OF CHRONIC POSTERIOR URETHRITIS CAUSING INTERMITTENT GLEET.

By H. M. CHRISTIAN, M.D.,

Adjunct Professor Genito-Urinary Diseases, Philadelphia Polyclinic; Chief Surgeon Genito-Urinary Dispensary, University of Pennsylvania.

By the term intermittent gleet is meant a urethral discharge, recurring at repeated intervals, very often without apparent exciting cause. The condition is a very common and troublesome sequel of acute gonorrhea, being

frequently found to occur in cases where the acute disease seems to have been cured. It depends primarily for its cause upon the presence in the urethra of one or more sharply defined areas of "intense congestion, excoriation, granulations, and epithelial thickenings" (White and Martin).

In the treatment of this most troublesome affection the first essential requisite is that the physician should be able to definitely determine whether the seat of the disease is located in the anterior or posterior urethra.

The writer recalls the fact that up to a comparatively recent period all cases of gleet were considered to be dependent upon lesions in the anterior urethra, generally stric-

tures, so called, of large caliber, no regard whatever being paid to the posterior urethra. At the present day, however, genito-urinary surgeons are convinced of the fact that fully one-half, if not more, of all cases of intermittent gleet discharge depend upon the presence of chronic granular patches located in the deep urethra. In thirty-one cases of chronic urethral discharge, Finger found the posterior urethra affected in fourteen. White and Martin state that the seat of predilection for chronic urethritis is the posterior urethra. My own experience would go to confirm this last statement, as I found in sixty cases of gleet treated during the past year that the posterior urethra was the part affected in forty-four.

In determining whether a given case of gleet depends upon the presence of a chronic posterior urethritis, we should be guided by two things: first, the clinical history of the case, and second, the examination of the urine. As regards the clinical history, repeated recurrence of urethral discharge, not due to fresh infection, associated with increased frequency of urination, is presumptive evidence of trouble in the deep urethra. Turbid urine containing clap shreds passed by the patient after irrigation of the anterior urethra is of course absolute evidence of chronic posterior urethritis.

The successful treatment of this affection proves, too often indeed, to be a most troublesome problem, and extremely trying to the patience both of the surgeon in charge and the unfortunate victim of the disease. At the outset it must be borne in mind that there is no routine line of treatment for the cure of all cases. He who relies for success in the treatment of this disease upon the passage of a sound alone, or upon the marvelous efficacy of some potent clap injection, will surely fail. In few conditions is it more necessary for the physician to be a man of infinite resources. The treatment proper for chronic posterior urethritis should be both general and local. As regards general treatment, several important points must be looked after. Very many of these patients are rheumatic or lithemic. These conditions, if found, must of course be treated by the internal administration of suitable remedies and by regulation of the diet. Again, a large number of these patients are neurotic, pass urine filled with oxalates accompanied with excessive precipitation of phosphates, improperly called phosphaturia. For this condition I have found the following prescription very valuable:

- R Strychninæ sulph., gr. ss;  
Acid. phosphor. dil., f ʒ j;  
Ext. erythroxylon cocæ fl., q. s. f ʒ iij.  
M. Sig.: ʒ j t. i. d. after meals.

If, as so often occurs, these patients show signs of sexual neurasthenia, a general line of treatment for the purpose of toning up the nervous system is indicated. This should include outdoor exercise and gymnastics, and the internal administration of cod-liver oil, arsenic, and iron. The writer would call particular attention to the use of the freshly prepared undiluted nitro-muriatic acid, which he has so often found of great service. The formula used constantly by him is as follows:

- R Acid nitro-muriatic (U. S. P.), f ʒ iss;  
Tr. nucis vomic., f ʒ ss;  
Elix. cinchonæ, q. s. f ʒ viij.  
M. Sig.: ʒ ss in water after meals.

The local treatment is of course the more important element in the management of cases of chronic posterior urethritis. It embraces irrigation of the deep urethra; the passage of sounds; deep instillations; massage of prostate gland; the use of the psychrophore; and lastly, the application of medicated ointments to the mucous membrane of the deep urethra. I have placed these various modes of treatment in the order in which they will prove of the greatest utility to the general practitioner.

*Total Irrigation of the Urethra.*—This is the first line of treatment to be carried out in all cases, its employment being imperatively demanded to insure success. The use of ordinary hand injections for the cure of recurrent gleet dependent upon chronic posterior urethritis is absolutely valueless, for the simple reason that the seat of trouble, being in the deep urethra, and consequently behind the "cut-off" muscle, cannot be reached by such methods. In total irrigation of the urethra, however, this resistance of the compressor urethræ muscle is overcome; the medicated solution being thrown into the bladder acts directly upon the deep urethra as it passes in, and again upon being voided by the patient. Two methods of using total irrigation can be employed:

First, meatus irrigation. Here we depend upon overcoming the resistance of the cut-off muscle, by hydrostatic pressure. For this purpose is needed a fountain syringe fitted with a glass or hard-rubber conical nozzle such as is generally found attached to the nasal douche. To irrigate the deep urethra with this simple apparatus requires that the reservoir containing the irrigating fluid should

be suspended at a height of seven feet from the floor. Next the patient should assume a semi-recumbent position in a chair, the legs fully extended and widely separated (a steamer chair is admirably adapted for this purpose); the nozzle of the syringe is held firmly in the meatus and the fluid is allowed to *slowly* enter and distend the anterior urethra. In most cases the time necessary to overcome the resistance of the "cut-off" muscle is from one-half a minute to two minutes. The bladder should be filled at each irrigation, the patient passing the solution after treatment.

This is the method of applying total irrigation to the urethra that is most largely used by genito-urinary surgeons at the present day. It is a form of treatment that is by no means easy to carry out always. As a matter of fact, in some few cases it is next to impossible to overcome the resistance offered by the compressor urethræ muscle. Where such is the case, or where meatus irrigation is a very painful procedure, it is perfectly proper to use the soft catheter, carrying it down into the posterior urethra and allowing the irrigating fluid to pass through the catheter into the deep urethra and bladder.

In the writer's experience the drugs that have been most valuable in irrigation for chronic posterior urethritis are nitrate of silver and sulphate of copper; of these the silver salt is by far the more useful.

In every case of recurrent gleet where the two-glass test shows the seat of disease to be located in the deep urethra, the first routine treatment to be employed should be irrigation of the posterior urethra with a solution of nitrate of silver, beginning with the strength of 1:6000. Where it is practicable this treatment should be carried out daily for ten days, increasing the strength of the solution every three or four days—*i.e.*, first three days, 1:6000; then for three days, 1:4000; finally, 1:2000. Where it is impossible in private practise to use daily irrigations—and this will generally be found to be the case—treatment should be carried out twice a week, increasing the strength of the solution every week.

The writer has dwelt at some length upon this subject of total irrigation in the treatment of chronic inflammation of the posterior urethra, for the reason that he is thoroughly convinced, as a result of rather extensive experience, that it is the most important feature in the successful management of these most troublesome cases. The simplicity of the technique, the ease with which it can

be carried out, and above all the fact that as a routine treatment it is applicable to all cases and can never do harm—which is more than can be said for some modes of treatment—all contribute in the writer's mind to make irrigation of the first importance in the handling of these cases.

Second only to irrigation is the proper use of the steel sound. This instrument should never be used where there is a distinctly purulent discharge with cloudy urine. Finger lays great stress upon this point, which the writer has also found to be a most important one. Where irrigation has been practised for a week or ten days, and there is simply a scanty mucoid discharge at the meatus, the urine clear but filled with clap shreds, the sound passed every four days will prove to be a most valuable adjunct in the treatment.

Under these circumstances our custom is to begin with a 24 F. sound, following its withdrawal by total irrigation of nitrate of silver 1:4000. At subsequent visits the size of the sound is increased up to 28 or 30 F., each passage of the sound being followed by a total irrigation of silver, increasing gradually in strength from 1:4000 to 1:2000.

By this combined method of treatment a cure can be confidently expected in the majority of cases in from eight to twelve weeks. There will of course arise plenty of instances where its employment does not seem to be followed by any apparent results for the better. Here the use of the deep urethral instillator will often prove of great value. After passage of the sound, the deep urethral syringe holding about ten drops of silver or copper solution is introduced into the urethra and the solution is deposited in the prostatic portion, behind the compressor muscle. The strength of the first solution so employed should be one-per-cent. At the end of four or five weeks' treatment, as high as five-, eight- or ten-per-cent. solutions may be used.

Deep urethral injections must be at once discontinued if they are followed by violent reaction—*i.e.*, increased urethral discharge and continued vesical tenesmus.

In undertaking the treatment of chronic posterior urethritis, rectal examination should be a matter of routine practise in all cases. In many instances such examination will demonstrate that in addition to the lesions in the posterior urethra there are present also catarrhal prostatitis and chronic seminal vesiculitis. The prostate will be found to be larger than normal, soft and tender; moreover, the finger carried above the prostate

will often detect on either side an oblong, thickened, tender mass, which constitutes an inflamed seminal vesicle. Where these conditions are present massage of the prostate and seminal vesicles every five or six days forms an essential part of the treatment. Indeed, very many cases can never be cured permanently without this maneuver being practised. Massage should always be followed by total irrigation of silver.

The psychrophore, an instrument which has been advised in the treatment of chronic posterior urethritis, seems to the writer to be of little value in cases where persistent gleet discharge constitutes the prominent symptom. It is chiefly serviceable in those conditions of atonic impotence and sexual neurasthenia so often resulting from chronic inflammation in the deep urethra.

As regards the use of the urethroscope, medicated bougies and the introduction of powders and ointments into the deep urethra for the cure of this affection, but little of any value can be said. While all these methods have a distinct place in the treatment of chronic anterior urethritis, they can hardly be said to have been of any great service when applied behind the compressor urethræ muscle. As far as the urethroscope is concerned, it should be kept out of the deep urethra altogether. I cannot help but feel that there ought to be a future for the soluble medicated bougie in the treatment of these cases, but so far my experience with them has been very limited and very unsatisfactory.

In concluding, the following line of local treatment is strongly advised as being applicable in all cases of chronic posterior urethritis: For ten days or two weeks total irrigation of the urethra with silver solutions—1:6000 during first week, 1:4000 in the second week. If practicable, these irrigations should be employed daily; where this cannot be accomplished, one treatment every four days will answer. In the third week pass a sound every four days, and follow by an irrigation of silver 1:2000. Continue the regular passage of sounds, increasing in size up to 28 or 30 F., every four days, for a period of from three to four weeks.

Irrigate the urethra after each introduction of the sound. Where prostate is involved, supplement the above treatment by stripping of the gland per rectum once a week. This is most essential to success.

Under such a course of treatment one can confidently expect a cure in almost all cases in from six to ten weeks. One important

point should always be borne in mind, viz., where the symptoms are increased and the local condition made worse by treatment it must be at once suspended for a time. Particular attention is called to this matter by White and Martin in *Genito-Urinary and Venereal Diseases*, page 141, where it is stated that "if after two months' treatment there is no marked improvement, and particularly if coincidentally with active treatment the patient becomes worse, all applications and medication directed to the urethra should cease."

---

#### EXCISION OF THE THYROID GLAND.

---

BY THOMAS C. DETWILER, M.D.,  
Lancaster, Pennsylvania.

---

The thyroid belongs to the class of ductless glands. In health it weighs from one to two ounces and is of a brownish-red color. It is a bilateral gland connected in the median line of the neck by a narrow isthmus. In front it is covered by skin, the platysma and superficial fascia, the sternohyoid, sternothyroid and omohyoid muscles. Its lateral surfaces are in contact with the carotid artery and jugular vein on the outside, and inside with the trachea, larynx, and esophagus. Its blood-supply is very large. The superior thyroid arises from the common carotid, and the inferior thyroid arises from the innominate. Sometimes there is a median branch. The veins are very large, thin-walled, and form a plexus on the surface of the gland, and they form very many anastomoses.

As the scope of this article is too limited to refer to the various pathological conditions of the gland, I will immediately proceed to the indications for operation as given by Jacobson. Briefly epitomized they are as follows:

1. The failure of previous treatment.
  2. Dyspnea sufficiently constant to prevent the patient from following an active employment, or inability to bend the neck in sedentary employment.
  3. The existence of tracheal stridor or extension of the bronchocele downward.
  4. Attacks of sudden suffocation—dyspnea.
  5. Difficulty of deglutition.
  6. Steady or rapid enlargement with or without dyspnea, with threatened growth downwards and a tendency to become sub-sternal.
  7. To improve the personal appearance.
- It is needless, after what has been said

about the anatomical position of this gland, situated in the most dangerous part of the neck, surrounded by the most vital tissues, to point out that the operation should never be undertaken lightly, and when undertaken at all, only by a surgeon who has the utmost confidence in himself and is fully prepared to meet all emergencies. MacCormac once said the most difficult operation he had ever undertaken was the removal of a large bronchocele. The operation lasted over two hours and over one hundred ligatures were used. Still I feel assured that in the future many more thyroids will be removed than in the past, and the common sight of persons disfigured by an ungainly goitre will become exceedingly rare. Why wait for a growth to become a great disfigurement and a menace to life, when in proper hands an early operation will be practically without danger? Not wishing to seem radical, still I think all goitres in young persons, after proper treatment for six months or a year, that do not show a mark of decrease, or if there is any tendency to growth, should be removed.

The contraindications are:

1. High bronchoceles, especially if they are broadly fixed.
2. Calcified bronchoceles.
3. Those occurring in persons with ill-formed limbs.
4. Those that are substernal.
5. Those occurring in persons over fifty years of age.
6. Those occurring in persons with very feeble hearts—a very frequent occurrence in those suffering with bronchocele.

The dangers of the operation are:

1. Hemorrhage, which though great can usually be overcome by care. The danger from hemorrhage is not from the arteries but from the veins, which are unusually large and thin-walled, and in severe cases form a perfect network over the surface of the gland.
2. Injury to the recurrent laryngeal nerve, an accident that has happened a number of times. This danger gives every operator a great deal of anxiety until the fact has been ascertained that it has escaped injury.
3. Septic cellulitis. This most grave and fatal complication can now be almost entirely eliminated by careful attention to every aseptic detail.
4. Myxedema. This complication can be avoided by leaving a part of the gland and isthmus behind, as we are able to do in almost all cases; but if such should be impossible, I can see no reason why we should not

have as perfect control over this disease artificially induced as we have by the use of thyroid extract in idiopathic cases in general practise.

*The Operation.*—Place the patient on his back with a sand-bag or hard support under his neck, and the shoulders well raised. The chin should be kept in a line with the sternal notch. The anesthetist stands at the head of the table. Chloroform should be used, as ether causes too much engorgement of the veins of the head and neck.

A free incision should be made—an incision that will freely uncover the lobe. Kocher makes a Y-shaped incision, but generally this will not be necessary. A straight one or one slightly curved will usually answer, and the resulting scar will be almost hidden by the fold of the sternomastoid—a matter of no small moment with women patients. The skin, platysma and fascia are now divided. The veins that are met with are secured between double ligatures and cut; the muscles on the surface of the gland are ligated and divided. They are often very thin from being stretched over the enlarged lobe. If necessary the sternomastoid may be cut, but it can generally be separated and pressed to one side with the carotid artery and the jugular vein. In dissecting out the lobe use an Allis blunt dissector or a periosteal elevator. In employing these instruments absolutely no violence must be used, but the utmost gentleness. A blunt-pointed pair of scissors curved on the flat will be found very useful. Use the knife as sparingly as possible; the handle will be much more useful than the blade. Cut no tissue until it has been thoroughly examined—a vein on the stretch can easily be overlooked and cut. The amount of hemorrhage from even a small vein is truly surprising. It is a good plan to frequently raise the head so that the veins can fill and become easily visible. The veins form a plexus over the lobe and each must be secured between double ligatures and cut. Hemostats cannot be trusted as in most cases the vein walls are too thin to hold. Step by step the front of the gland is cleared. The next step is to clear the lateral margins and ligate the arteries. The superior thyroid is much the easiest to secure, entering the gland from the top. Secure it between double ligatures, and cut, using an aneurism needle if necessary. The next step varies according to the operator, Treves going down and tying the inferior thyroid and the median if it exists. Jacobson urges

attacking the isthmus, which is probably the better plan. A steel director is passed between the isthmus and the trachea, and it is either ligated as a whole or cut, and the bleeding points ligated as found. The hemorrhage in either case, with care, is trifling. It will be found a good plan when ligating the isthmus to leave as much healthy gland tissue as possible encroaching on the tumor as far as the healthy tissue will admit. By doing this, if it is necessary to remove both lobes there will still be left the isthmus and a little healthy gland tissue on each side, and so the danger of myxedema will be avoided. The gland is now turned from side to side, lifting it from its bed slowly, proceeding downward. Make as little traction on the trachea as possible in freeing the internal lateral surfaces, as it is apt to cause intense dyspnea. The attachment between the lobe and trachea is often very firm and requires the use of knife or scissors frequently. Ligate each bleeding point as it appears until the lower limit of the growth is reached, when the most dangerous and difficult part of the whole operation is before us, namely, ligating the inferior thyroid and endeavoring not to injure the recurrent laryngeal nerve. Baumgartner and Cr  d   recommend ligating the branches of this artery as it enters the under part of the gland, as by so doing one is as far as possible away from the nerve. MacCormac also thinks well of this plan.

The gland being removed, and all bleeding stopped, close the wound with silkworm-gut sutures. Lightly pack the lower part of wound with sterile gauze for drainage. After applying the dressings the best way to retain them in position is by a bandage from the axilla below to the chin and head above, firmly stitching it to keep it in place. In case there is enlargement of both sides the surgeon is not justified in immediately removing the other side, but should wait for two or three months to see what effect the work already done will have on the remaining lobe. I have no theory to offer or explanation to give as to the why or wherefore, but the fact remains that when one lobe is removed the other frequently atrophies. This is well illustrated in the following case:

M. P., aged twenty-two years, of healthy parents; one brother and seven sisters, and all healthy. There is no family history of goitre. When ten years old first noticed growth in neck. It grew slowly but steadily. Did not respond to any treatment. When he was first seen he had a brassy tone of voice,

husky, brazen cough, and had had three attacks of suffocative dyspnea, one that almost proved fatal. Had coughing attacks that compelled him to rush into the open air to try to obtain relief. Had great difficulty in bending his head in order to follow his trade, that of a cork-cutter. His neck measured  $17\frac{1}{2}$  inches in circumference, which he could increase to 24 inches by straining. Both sides were about equally enlarged. The growth was soft and elastic, with ill-defined borders, extending from the angle of the jaw to the sternum.

On August 24, 1897, assisted by Dr. Theodore B. Appel, Dr. J. H. Musser giving chloroform, he was operated on. A goitre six inches in length by eight inches in circumference was removed from the left side of his neck. The fact that he could distend his neck from  $17\frac{1}{2}$  inches to 24 inches indicates the condition of the vein walls. Some of them seemed as thin as tissue-paper. It was absolutely impossible to use a hemostat, but each vein had to be ligated, using very great care not to tie too tightly as the catgut would cut through. The hemorrhage from a broken vein was very great, but we succeeded in removing the whole lobe with the exception of some healthy tissue, which was left with the isthmus. In the near future we intended to remove the right side, which was fully as large as the left.

The wound was closed with silkworm-gut sutures; iodoform gauze was lightly packed in lower part of wound for drainage. About two hours after operation I was hastily called to the hospital and found there had been a most profuse hemorrhage. Quickly cutting all stitches I opened the whole wound, turned out a large blood-clot, and found the ligature had slipped from the medium thyroid artery. It was easily picked up and again ligated. The wound was hastily closed, an intravenous injection of a pint of normal salt solution was done, and from a pint to a quart of the same placed beneath skin of breast and back. It was quickly absorbed. The patient rallied nicely and was discharged from the hospital in two weeks with the wound perfectly healed, save the lower angle where the drainage had been.

Within two weeks after leaving the hospital the decrease in the other lobe was readily perceptible, and within three months the growth had almost entirely disappeared. For a few months he was unable to speak in a loud tone of voice, but now he has fully regained his former volume of speech.

**ANESTHESIA AND ANESTHETICS, WITH  
A PLEA FOR THE MORE GENERAL  
EMPLOYMENT OF CHLORO-  
FORM AND ETHYL  
BROMIDE.**

BY FRANK C. HAMMOND, M.D.,

Instructor of Gynecology in the Jefferson Medical College;  
Anesthetist to the Gynecological Clinic, and Assistant  
in the Out-Patient Department for Diseases of  
Women, Jefferson Hospital, Philadelphia.

Much has been written—both in text-book and journal—in regard to anesthesia and anesthetics. Though the writer does not purport to set forth new theories, he will endeavor to call attention to a few practical facts, and make a further plea for the more general employment of chloroform and ethyl bromide.

The advancement and progression of this department of surgery presents for our consideration practically three drugs, and one gas, in order of their safety as follows: nitrous oxide, ether, chloroform, and ethyl bromide. The latter three are in liquid form, and have been used mostly alone; but solutions of these together, and with other drugs added, have been used from time to time, and still are in some localities very popular. The combinations of these various drugs have been erroneously called *mixtures*, for they are true *solutions*.

The various solutions of chloroform with ether, etc., are used with the idea of escaping the dangers of chloroform when used alone. They first received encouragement and recognition from the report of the chloroform committee of the London Medico-Chirurgical Society about 1862, who declared their superiority in point of safety.

No drug has yet been used for producing anesthesia that has not caused death.

Without doubt the success of securing an anesthetic with the least danger consists in adapting the boiling point of the narcotic to the temperature of the body. Many experiments based upon this theory have been made, the latest of note being those of Schleich. He has prepared three formulæ, the one designated as No. 3 being advocated for general use. It consists of chloroform 30 Cc., petroleum ether 15 Cc., sulphuric ether 80 Cc. Dr. Willy Meyer recently read a paper before the Medical Society of the County of New York advocating its use. The Esmarch inhaler was used for the administration.

Dr. Meyer summed up by stating: (1) During the induction of anesthesia there was

no salivation, and rarely any accumulation of mucus in the trachea, and no cyanosis. (2) That during the stage of anesthesia rarely was there noticed any accumulation of mucus in the trachea, and no cyanosis. (3) The patient awakened more rapidly than from ether or chloroform narcosis alone. One drawback is the chlorine odor.

Ether, though recognized by the profession universally as the least dangerous liquid anesthetic, has its objections, and in some localities, viz., the Southern and Western States, is almost entirely supplanted by chloroform, or the A. C. E. mixture.

Statistics have been published from time to time to show the relative dangers of one anesthetic to another. These are imperfect at best, because there is no contradicting the fact that unreported deaths have occurred, for surgeons do not rush to record their mishaps and fatalities. Gurlt\* of Berlin gives a series of 51,846 cases for the year 1893: 32,723 were chloroform administrations, 11,617 of ether, 3896 with ether and chloroform, 750 with Billroth's mixture (A. C. E.), 2769 with ethyl bromide, and 91 with nitrous oxide. The total fatalities were twenty, and of these seventeen were due to chloroform. The average death-rate was 1 in 2587 administrations. The death-rate from chloroform was 1 in 1924 administrations. The statistics were compiled from sixty-three reports, twenty-one of which had been sent from fifteen German university clinics.

Judging from collateral reading and personal conversation with men who have pursued medical studies abroad, the foreign statistics absolutely fail to do justice to chloroform, the whole fault being due to the method of administration. The general custom is to cover the face with a folded towel, and administer it in much the same manner as they use ether, the towel frequently being held down upon the face. Such being the case the high mortality is readily accounted for. Chloroform, if carefully and properly administered, and the patient closely watched, should not give rise to the untoward symptoms so often reported.

Silk† was very much struck with the fact that the majority of fatalities occurred in the hands of men who had been graduated but a year or two. It seems to me this must refer to those men who have not had the opportunities afforded by serving as an in-

\* THERAPEUTIC GAZETTE, Aug. 15, 1894.

† The Lancet, April 28, 1894.

terne in a hospital, or reaped the benefits derived from the material proffered by their preceptor. This deplorable condition is due to the lack of systematic, practical teaching in anesthetics and anesthesia in the curriculum of our colleges, and certainly affords a most powerful argument for a more practical course in this very important subject.

Anesthetizing is looked upon by some as a menial position, but on the other hand a careful administrator is a respected man, and one in whom we can place every confidence; and his position is always a very responsible one.

"All's well that ends well" is a true saying, but when difficulties arise it is the experienced man that knows best how to meet all emergencies. "Practice makes perfect;" this especially applies to the administration of an anesthetic. The administrator should attend strictly to the patient, and be entirely oblivious of the operation. He should carefully watch the respiration, pulse, and general condition. Nothing is more objectionable or uncalled for than to push an anesthetic during the first stage of anesthesia—that is, prior to the destruction of consciousness. The smothering, strangling sensation so produced will be ever uppermost in the patient's mind, especially so if he or she has previously taken an anesthetic which was carefully administered.

The following are a few general rules which should be observed:

1. Whatever anesthetic is used, ethyl bromide excepted, begin it slowly, and *do not "push it" until the strangling, choking sensation has passed.*

2. Should the irritant cough occur, allow a little pure air to be breathed, and proceed slowly.

3. If rapid swallowing intervenes during the first stage, proceed slowly with the administration.

4. Should the patient struggle, do not allow those standing around to "throw" themselves over the chest and abdomen, as this seriously interferes with respiration. Oftentimes the patient can be restrained by simply bearing down on the shoulders. If necessary hold down the arms and legs, but keep off the chest and abdomen.

5. Inspire your patient with confidence by a few cheering words prior to beginning the administration, as it oftentimes quiets an otherwise nervous individual.

6. Watch carefully the respiration; see that air is passing in and out of the lungs without obstruction. Anticipate cyanosis by

carefully observing the color of the cheeks, lips, and ears.

7. Keep track of the pulse with a finger either on the radial, temporal, or facial artery. Note whether it is slow and full, or rapid, running, and weak.

8. *Keep the mouth shut*; this is the best prophylaxis against the patient "swallowing the tongue." Hold the lower jaw in contact with the upper with your hand throughout the entire anesthesia—that is, until the patient is removed from the operating table.

My method is as follows, and since adopting it the untoward symptoms have been reduced to almost *nil*, and the tongue forceps practically discarded, although it is always safe to have a pair at hand: The ring and little fingers of the one hand are "hooked" under the inferior maxilla, just to the right of the symphysis menti, if the right hand is used, and to the left thereof if the opposite hand is employed. The thumb is placed across the nose at its base, and assisted by the first and second fingers, maintains the cone in its position over the nose and mouth. If the little finger is allowed to slip backward the pulsations of the facial artery can be distinctly felt as it passes over the border of the jaw, at the anterior edge of the masseter muscle. The remaining hand is then entirely free. Although somewhat tiresome, especially during a prolonged anesthesia, still this method of keeping the mouth closed is, as stated before, the best prophylaxis against the dropping backward of the tongue in the pharynx, with its accompanying train of symptoms, as obstructed respiration, cyanosis, etc.

The following may be practised, especially when chloroform is being administered by means of a towel: Place your forearm over and above the face of the patient, with the back of the hand arched upward in such a manner that the palmar surface of the hand will be to one side of the nose and the fingers separated, and to one side of the mouth, the first finger being curved around the lower lip. Extend the fingers far enough to enable the tips to "hook" over the inferior maxilla, to one side of the symphysis menti, and in this manner hold the mouth shut. The thumb should be allowed to project over the nose about its middle third. The nares and mouth will thus occupy a free breathing space formed by the thumb on one side, the index-finger on another, the remainder of the arc being open. The towel (a single layer only being employed) should be spread over the face; the arm and hand, in addition to the

method already mentioned, will also serve to keep it a sufficient distance from the skin, and permit of a bountiful circulation of air. What is gained by this method? The mouth is kept closed; the breath as it strikes the fingers during expiration can readily be detected, and the respiration thus noted; the towel does not come in contact with the face, hence burning of the skin is obviated; and a sufficient quantity of air is allowed to circulate under the towel.

Remember that the epigastric region may rise and fall and still no air pass into the lungs. This is an important point. The obstruction may be due either to dropping back of the tongue or an accumulation of mucus in the pharynx, larynx, or rarely the trachea. If due to the former, open the mouth by depressing the lower jaw, using a mouth-gag if necessary, and seize the tongue with a pair of "tongue-holding forceps," and draw it forward, then close the mouth and keep it closed. Use the variety of forceps that has one fenestrated blade, or Houze's tongue-holding forceps. Under no consideration use the type of forceps in which one blade is pivot-shaped and punctures the tongue; this procedure is barbarous, and entirely uncalled for. Passing a piece of silk through the tongue with a needle, and by this means holding forward an incessantly receding tongue, should also be relegated to the past. The best prophylaxis against a receding tongue is to keep the mouth shut from the beginning, and permit respiration only through the nostrils. If mucus accumulates in the pharynx, clean it out. Another method of bringing the tongue forward is to seize the angles of the lower jaw on either side and gently pull it forward; by this procedure the condyle of the lower jaw is "thrown," so to speak, on to the eminentia articularis. This movement will invariably bring forward the tongue, and remove the obstruction which has impeded respiration. If the tongue persists in dropping back, turn the head to one side; if this fails, allow the head to remain in the same position and hold the tongue forward. It will rarely be necessary to resort to the latter procedure.

9. Always protect the eyeball. Place a single layer of towel over the eyes, and hold it there with the inhaler that is being employed. If administering the anesthetic on a towel, use another towel for the ocular protection. This will prevent the vapor from irritating the sensitive cornea and conjunctiva.

Never touch the eyeball to ascertain if narcosis is complete, as it is unnecessary, and has caused not a few attacks of conjunctivitis and suppurating keratitis. Simply press the upper eyelid down gently on the eyeball; if the patient makes no attempt to close the eyelids, then insensibility is complete.

10. Never administer an anesthetic to a female unless another person is present; this should be imperative.

11. Should vomiting begin push the anesthetic. During the act of emesis, prevent the tongue from slipping back into the pharynx. After vomiting ceases remove the accumulated ejecta from the mouth and pharynx. If the site of operation is above a line drawn around the chest, at the level of the nipples, turn the head to the opposite side, in order to prevent the ejected material gaining access to the wound.

12. Dilated pupils failing to respond to light signifies deep anesthesia; stop the narcotic. Dilated pupils which respond to light are significant of one of two things—"coming out" of the anesthetic, or passing into the stage of deep anesthesia. A narrow, contracted pupil is a warning of danger.

*Nitrous Oxide.*—Having had no practical experience with this agent I do not feel qualified to discuss it. My friend, Dr. Charles McNeille, of New York, tells me that the majority of dentists while operating on patients under the influence of this gas throw the head backward into almost complete extension, and invariably cyanosis is present. He obviates this by throwing the head forward in flexion. Mention of this is made, as it may prove a valuable point.

*Ether.*—The safest preparation of ether by far is the product of the laboratory of E. R. Squibb & Son. Without doubt ether is the most universally used anesthetic, but it has its shady side of mortality. To its disagreeable odor and nausea is due the fact that it is abhorred by the laity. It is rare not to have nausea and oftentimes vomiting following its use. Should the patient be properly prepared beforehand, these disagreeable and at times dangerous after-effects are reduced to a minimum.

*Contraindications to the use of ether:* The first of these is in renal disease. (Hare states that quantity for quantity chloroform is more irritating to the kidneys than ether, but as a much larger quantity of the latter would be used the former is to be preferred). A second contraindication exists in those who

have previously borne it badly; in atheroma, owing to the prolonged struggling under this narcotic, it had best not be used. In very aged persons with emphysema, asthma, chronic bronchitis, old pleurisy, cardiac hypertrophy, fatty heart or valvular lesions, ether is dangerous; and in habitual drunkards, or persons who drink in small quantities but frequently during the day, and in limited action of the lungs from adhesions caused by an old pleurisy or pneumonia, it is an unsafe anesthetic.

In the administration of ether either a towel or an inhaler can be used. The former should be folded to simulate a cone, allowing a small opening to remain at the top, so that the ether can be poured on the "cone" without removing it from the face. A formal inhaler is to be preferred, especially the one suggested by Dr. Oscar H. Allis, and described by him in the *Philadelphia Medical Times*, No. 162. The collapsible variety of inhaler is, however, unsatisfactory, as a great deal of ether is wasted, and a longer time is required to place the patient under its effects. A suggestion in regard to "lacing" or "threading" the inhaler may be made: The bandage that is used should preferably be doubled; this obviates the great amount of space between each layer, and presents a larger area for the evaporation of the drug, and when poured on it is not so apt to drop through on to the face. The bandage should always be renewed after each individual usage. A piece of gauze should be placed across the metallic face-piece, next to the bandage, as this affords double protection.

In administering ether always begin slowly, increasing it gradually, but as stated before, do not push it until the suffocating sensation has passed. Should the time consumed to place the patient under its influence be prolonged, then a few drops of chloroform will prove efficacious; this also applies to those cases that prove pugnacious under its exhilarating influence. If the patient bears the ether badly, which condition is manifested by the constant cyanosis, or should the respiratory tract become so filled with mucus as to form an impediment to breathing, then chloroform should be substituted.

**Chloroform.**—This drug has been much abused by the profession at large, and earnestly condemned, more however on theoretical grounds than practical observations. The high mortality in comparison to ether is due not so much to the drug, but the careless manner in which it is administered. In reviewing the tables of death, the causes in

the majority of cases are fatty degeneration, endocarditis, and other organic lesions, a few from "collapse," and in other cases the cause not given. *Quite a number of the patients have been under the care of a dentist.* Very few of the dental colleges include the teaching of the use of anesthetics other than nitrous oxide; hence a large majority of the graduates of dentistry leave their alma mater with little theoretical and no practical knowledge. Is this not sufficient argument for the high mortality referred to this agent? Indeed, graduates of dentistry should not be permitted to administer an anesthetic other than nitrous oxide, for owing to the lack of primary teaching they are entirely incompetent.

Chloroform is an ideal anesthetic, and if properly administered and carefully watched the majority of the untoward symptoms so often referred to will be eliminated. If the graduates of to-day would only pay more attention to the administration of an anesthetic during their collegiate course, chloroform would be more extensively employed and skilfully administered.

Practically there are no contraindications. It should be used when ether has been previously borne badly. It is the typical anesthetic for children and in obstetrical practise. It may always be employed in operations around the mouth and face when the actual cautery is to be used, and in the conditions given under the head of "contraindications" to ether.

In the administration of chloroform it is advisable to spread cosmoline over the face, around the nose and lips, to prevent burning of the skin, should the fluid drop thereon; but if due care is exercised this procedure may be dispensed with. Do not use a cone or conical shaped inhaler. The Esmarch inhaler is to be preferred. One just as good and giving every satisfaction, and far cheaper, can be made as follows: Procure a large-size gauze wire tea-strainer, with a long wire handle; cut to its shape a piece of merino, allowing sufficient edge to make a hem, pass a draw string through the hem, tighten, and fasten the strings to the handle. In the Esmarch inhaler a lady's handkerchief properly folded can be readily utilized for a covering. The bottle containing the drug should have but one tube passing through the cork—metal tubing preferable to glass. When a single tube is used the drug *drops* out, when two tubes the fluid *runs* out, and it is impossible to gauge the amount being

used. A single layer of a towel as previously described is efficacious.

Do not apply more than two or three drops at the beginning, then gradually increase until anesthesia is produced. Watch the respiration carefully. A few short inspirations, or holding the breath for a while, is sure to be followed by a full, deep inspiration; and here is where a great danger lies, for in this deep inspiration an overdose may be taken. To guard against this is easy; simply watch for it, and when it appears withdraw the chloroform. Remember that the danger from chloroform is often from an overdose, but that the overdose does not consist entirely in the quantity that may be taken during the administration, but often in the quantity that is taken at any one inspiration—in fact, to the suddenness with which the drug is introduced into the blood, and the concentrated form in which it arrives in the brain, producing paralysis of the respiratory center.

Lentz & Sons, of Philadelphia, make an apparatus by which oxygen is impregnated with chloroform, and is alluded to as "oxygenated chloroform." It consists of a forty-gallon cylinder of compressed oxygen. From this cylinder the oxygen is conveyed through rubber tubing to a graduated wash bottle, containing chloroform. The oxygen is introduced of course below the level of the chloroform, the gas passing through the liquid, and out of the bottle through another rubber tubing to the inhaler. The modified inhaler of Downes should be used in preference to the original, with the rubber-bag attachment. By changing the tubing, chloroform can be shut off, and pure oxygen administered. By this method the patient is more readily placed under its influence. While under its narcotic effects the general systemic condition is better than that of any other anesthetic, anesthesia can be maintained for a longer duration with a minimum amount of shock, and the subsequent nausea is rarely present, and then very slight.

In children chloroform is quicker, more reliable, and always to be preferred. A few whiffs, and the resisting struggles are allayed.

In obstetrics chloroform is used with comparative safety to the mother, although a few deaths have been reported, and is to be preferred to ether, even in long and instrumental labors, notwithstanding the fact that some observers under these conditions believe ether safer to the child. The employment of this drug during labor should be limited

to the second stage, excepting in primiparæ when the pains of the first stage become excruciating and unbearable. It should be administered during the pains, and suspended during the intervals—just a sufficient quantity to take off the keen edge of the pain. Experience has proved that anesthetics do not arrest the contractions of the uterus, but weaken the normal resistance of the perineal muscles, unless during its administration complete insensibility should be induced. The anesthetic so employed has no untoward effect on mother or child.

The employment of a narcotic of this kind, especially in primiparæ, has a tendency to quiet the overexcited and nervous condition, which will prove a large element in the successful conduct of the labor. The drug should not be administered during the third stage; its value ceases after the expulsion of the child. The proper use of the drug does not necessarily favor post-partum hemorrhage.

*Treatment of Impending Death.*—First remove the inhaler, and lower the head by elevating the foot of the table. Draw the tongue forward, and allow it to recede, about sixteen times per minute. For the pulse give a hypodermic of strychnine sulphate,  $\frac{1}{16}$  to  $\frac{1}{8}$  grain, *pro re nata* till an effect is produced. As a rapid stimulant a hypodermic injection of aqua ammonia may be given in the buttock, although this makes a slough; hypodermic injections of atropine sulphate,  $\frac{1}{16}$  to  $\frac{1}{8}$  grain, should be given *pro re nata* till an effect is produced. If the respiration has ceased, give a hypodermic of atropine sulphate,  $\frac{1}{16}$  to  $\frac{1}{8}$  grain, and repeat as often as necessary. Give a rectal injection of turpentine (this has often started a suspended respiration; stretching the sphincter and also has a favorable influence), and establish artificial respiration by instituting the Sylvester-Hall method.

Do not continue an operation immediately after the patient recovers, but wait until the pulse and respiration have been energetically restored. Unlike ether, *chloroform gives little or no warning*; the symptoms which usually occur to warn one are sudden paleness or lividity of the countenance, with shallow breathing, absence of or a rapid running pulse. The patient presents the condition of complete collapse and relaxation.

*Ethyl Bromide.*—This drug is very seldom used at the present time owing to the reluctance with which the profession accepts it. In the hands of Dr. E. E. Montgomery and others it has proven satisfactory, and he has found a field for its employment. It is a hy-

drobromic, or bromic, ether, an inflammable, volatile liquid, with a burning taste, and an odor not unlike chloroform; its boiling point is  $38^{\circ}$  to  $40^{\circ}$  C. This is not ethylene bromide, which is poisonous. It is not caustic, nor even irritant, when compared with chloroform, and can be ingested without difficulty. This drug is supposed to possess properties intermediate between those of chloroform and ether. Dr. Laurence Turnbull was the first to experiment with this ether upon man. He makes the following statement:\* "I found it was colorless, with an agreeable odor and pleasant taste, the boiling point  $40.9^{\circ}$  C., and its density heavier than water. When inhaled it produced more of the agreeable effects of chloroform, and did not increase the pulse over its normal beat, whilst its action was very rapid. It leaves an odor of mustard to the body. There is a pricking feeling of the skin at the elbow and in the hands, with a rapid loss of power to move; the skin is in a few instances moist, but in the majority of cases is natural. It differs from ordinary ether in the stage of excitement being short, the sedation and subsequent elimination rapid."

My observations from the use of this drug as an anesthetic substantiate the above, with the following addition: There is a primary dilatation of the pupil, and the eyes are suffused and congested, which condition passes away in a few minutes. I have given it for gynecological examinations, reducing dislocations, or any other procedure likewise short in duration. I have frequently administered it to children when rapid dilatation of the tear ducts was done.

In the administration of ethyl bromide I use a folded towel, pour about half a teaspoonful on, and apply this to the nose, holding the edges of the towel close to the face, and add the same quantity every few seconds until narcosis is produced.

Various methods have been used to prevent the nausea subsequent to the administration of an anesthetic. The most favorable seems to be the inhalations of oxygen, which are given immediately after the patient is placed in bed.

To conclude, an earnest plea is made for the more general employment of chloroform, and also for ethyl bromide. With the latter, owing to the very limited time required to produce its effects, the post-anesthetic symptoms are practically *nil*, the

patient reacts very readily, and is able to resume routine duties within a short time after consciousness is restored. Above all self-confidence is needed; keep a cool, clear head, and be prepared to meet any emergencies that may arise.

1420 TIoga STREET.

### A CASE OF THYROIDECTOMY.

BY WILMER KRUSEN, M.D.,  
Instructor in Gynecology, Jefferson Medical College; Assistant Gynecologist, St. Joseph's Hospital; Gynecologist, Charity Hospital, Philadelphia.

The following case is reported because of the marked severity of the symptoms produced by a tumor of moderate size, and because the operation of thyroidectomy is sufficiently dangerous to make surgical interference the subject of earnest consideration. The close proximity of vital structures, the possibility of sudden and profuse hemorrhage, the difficulty of preserving asepsis near the mouth, and the caution required in administering a general anesthetic, all combine to make the operation a serious one. But in cases where the symptoms are urgent, relief is imperative. The encouraging statistics placed on record by Kocher in 1895, of nine hundred cases of benign goitre upon which he had operated with a mortality of but one per cent., associated with the admirable results obtained by Kronlein, Sulzer, and others, influenced the writer in advising operation in the case detailed. The unsatisfactory results obtained by the use of such internal remedies as iodine and its compounds in cases of long standing, and the real though moderate danger in using injections of iodine, iodoform or ergotin into the gland, make the surgical method of treatment practically the only one that relieves the patient. The history of the case is as follows:

Mrs. S. K., German, housekeeper, aged fifty-three years. For the past two or three years the patient had noticed a gradual, painful enlargement of the right lobe of the thyroid gland; more recently, disagreeable symptoms had developed; and at the time of the first examination she was suffering from marked venous congestion of the face, frequent attacks of faintness and cardiac palpitation, insomnia, hoarseness, and an irritating cough evidently due to pressure on the recurrent laryngeal nerve; there was no difficulty in swallowing, and dyspnea was marked only on exertion.

\*Anæsthetic Manual.

The hypertrophied gland, about the size of an orange, on the right side of the trachea, extended laterally beneath the sternomastoid muscle and downward into the supraclavicular space, was freely movable beneath the skin, and apparently semi-cystic in character. The pulsation transmitted from the underlying carotid vessels was very evident on inspection and palpation. No organic cardiac disease was present, but the patient was extremely nervous and vasomotor phenomena were marked.

The operation of enucleation was performed at St. Joseph's Hospital, Philadelphia, on January 7, 1897. The anesthetic used was oxygenated chloroform. After thoroughly asepticizing the neck, an incision about four inches in length was made along the anterior border of the sternomastoid muscle, ligating before cutting the anterior jugular vein and exposing the bluish-white capsule of the tumor; the overlying tissues were slowly incised, and every bleeding point grasped with a hemostat as soon as cut, in this way avoiding copious hemorrhage. The growth was enucleated with the fingers and the Allis dissector, first from beneath the muscle, working from the muscle toward the trachea and exposing the carotid artery for two and one-half inches; extreme care being taken to avoid injuring the recurrent laryngeal nerve. The tumor was luxated forward and the isthmus forming the pedicle was ligated in sections with strong chromicized catgut, and the gland removed, leaving sufficient stump beyond the ligature to prevent the retraction of the tissue and subsequent hemorrhage. Every bleeding point was carefully secured and ligated with fine catgut, the wound freely irrigated with hot water, a drainage tube and strip of iodoform gauze introduced, and the external incision closed with interrupted silkworm-gut sutures.

The most alarming symptom during operation was the interference with respiration produced by the tugging on the trachea during the enucleation. For the first forty-eight hours after operation the pulse was weak and quite rapid, ranging from 130 to 150 per minute. This was treated by the use of atropine and strychnine, and the subsequent convalescence was uneventful, the patient leaving the hospital on the eighteenth day after the operation. No contraction or deformity has resulted from the scar, and the health of the patient at the present time is excellent.

# THE IMPORTANCE OF THE EARLY RECOGNITION AND TREATMENT OF ACUTE INFLAMMATORY GLAUCOMA.\*

BY CLARENCE A. VEASEY, A.M., M.D.,  
Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic; Demonstrator of Ophthalmology, Jefferson Medical College; Chief Clinical Assistant to the Ophthalmological Department, Jefferson Medical College Hospital; Consulting Ophthalmologist, Philadelphia Lying-in Charity, etc.

The importance of the early recognition and treatment of acute inflammatory glaucoma is universally acknowledged among physicians who have to do with ophthalmic work. But that some of us fail to recognize its importance is evidenced by the fact that occasionally patients are seen in whom the acuity of vision has been much reduced, or even totally abolished, because the disease had existed for some time before it was sufficiently recognized for the proper treatment to be instituted, or because of the use of the mydriatics, either being an almost fatal error as far as the patient's vision is concerned.

It is just as important that the general practitioner be thoroughly familiar with the symptoms and treatment of this condition as it is for the ophthalmic surgeon, because in the majority of instances he is the first to be applied to for relief; and the condition is one that if not quickly recognized and the proper treatment instituted the patient's visual acuity usually suffers great damage.

The writer does not propose to discuss the many theories that have been suggested as to the etiology of the affection. Suffice it to say that whatever the primary cause may be, it is believed that the mechanical cause is the blocking up of that angle of the anterior chamber known as the "filtration angle," and that it is kept up to a considerable extent by the crowding into it of the iris.

A number of prodromes, by no means constant, are occasionally found to precede the appearance of the glaucomatous attack. It is stated that a desire to change one's reading glasses more frequently than is usual should be regarded with suspicion. Attacks of "foggy vision," though lasting for a few moments only, perhaps accompanied by slight injection of the eyeball, and the appearance of a halo of colors around artificial lights, are sometimes met with and are sufficient in themselves to cause a very careful examination to be made of the eyes and more se-

\* Read by title at the forty-eighth annual meeting of the Medical Society of the State of Pennsylvania.

vere symptoms watched for, and, if possible, guarded against.

The attack of acute inflammatory glaucoma usually presents a combination of symptoms so thoroughly characteristic of the affection that with the exception of a few extremely rare instances it should never be mistaken for any other disease. Appearing as it does very frequently at night (and there seems to be a marked tendency to occur in the latter part of the night or early morning), there is ordinarily excruciating pain throughout the side of the head, which is sometimes accompanied by nausea and vomiting. The extremities may be cold, or there may be even flushing with slight fever. These symptoms are apt to cause the uninitiated to suspect some severe constitutional origin, but if the eyes be carefully inspected there will be found some swelling of the lids and some edema of the subconjunctival tissue. The eyeball will be intensely injected, and the cornea will in most instances be hazy and partially anesthetic. The appearance of the latter can be compared to a piece of cold glass the surface of which has been breathed upon, and if its sensibility be tested by widely separating the lids and touching it with a wisp of absorbent cotton, it will be found that the impulse to close the lids that exists in normal eyes is entirely absent, or not so decided as usual, according to whether total or partial anesthesia is present. The aqueous humor is more or less turbid and the anterior chamber as a rule is much more shallow than normal. The pupil, which is one of the chief points of difference between this and certain other affections with which it is mostly confounded, is dilated either moderately or widely, and if it reacts at all does so extremely sluggishly. The iris is discolored, and if the tension of the eyeball be tested by palpation through the closed lids with the index-fingers of both hands, it is found to be elevated—that is, the eyeball is harder than its fellow, or if the latter be also affected, harder than an eye the tension of which is known to be normal. The patient's visual acuity is greatly reduced, oftentimes only the ability to distinguish between light and darkness remaining, and if an attempt be made to examine the interior of the eye with the ophthalmoscope it is found impossible to get any view of the fundus.

If no treatment be instituted these symptoms may last from a few days to a few weeks, and when the eye recovers it is found that the visual field is somewhat contracted, the

iris less mobile, central vision less acute, the optic nerve slightly cupped, and the tension more or less elevated. It is rare for a patient to become permanently blind in the first attack; but experience teaches that the attacks recur with increasing frequency, each one leaving the vision worse than before, until total blindness ensues, resulting in the condition known as *glaucoma absolutum*.

The two diseases with which acute inflammatory glaucoma is most likely to be confounded are acute conjunctivitis and acute iritis, and if the treatment of iritis be instituted in a case of glaucoma, or *vice versa*, much harm may, and probably will, result therefrom. Acute inflammatory glaucoma presents a sudden onset, a rapid reduction of the visual acuity, a hazy and more or less anesthetic cornea, a widely dilated pupil responding very sluggishly if at all to the various reactions, and elevated tension. Acute iritis presents a gradual onset, not so marked a reduction of vision, as a rule, as in glaucoma, the cornea is not so hazy nor anesthetic, the pupil is contracted, and if the iritis has existed for a short time the iris is attached to the capsule of the lens, the tension remaining unaffected. Acute conjunctivitis presents no marked reduction in the visual acuity, no severe pain as is found in iritis and glaucoma, the pupil reacts promptly, and the tension is unaffected.

The treatment of acute inflammatory glaucoma is of two kinds, medicinal and surgical. The medicinal, if employed alone, is usually of temporary benefit only, surgical intervention being required to check the progress of the disease. Leeches applied to the temple and hot fomentations to the closed lids assist in reducing the inflammation and alleviating the pain, though if the latter be very severe hypodermic injections of morphine may be required. Rest in bed if the patient be in a weakened condition, the administration of nourishing diet and stimulants if required, darkening of the room if there be much dread of light, and the use of smoked glasses when out-of-doors, are measures to be advised. The internal administration of salicylate of sodium in large doses also seems to be of benefit in some cases.

The object of primary importance is of course to reduce the intra-ocular tension as rapidly as possible, and this may be attempted by medicinal or surgical measures. It seems to be good practise to instill into the eye a drop or two of the solution of eserine (about two grains to the ounce), or pilocarpine

(about four grains to the ounce), every half hour for six or eight hours, using at the same time a four-per-cent. solution of cocaine to assist in relieving the pain and to render the iris more susceptible to the action of the myotics; and if at the end of this period the pupil remains dilated and the tension still above the normal, it is better to adopt some surgical intervention at once. If, on the other hand, the pupil responds to the action of the myotic and the tension becomes normal, it is not necessary to operate until the attack has subsided.

The operations that are performed for the reduction of intra-ocular tension are paracentesis of the anterior chamber, anterior sclerotomy, posterior sclerotomy, and iridectomy. The first of these is a temporary measure, but each of the last three has advocates who claim that it is curative. The writer is one of those who believe that a carefully performed broad peripheral iridectomy is the best of the measures in the majority of cases, and that it should be performed during the inflammatory stage if drugs fail to produce amelioration of the symptoms. If, however, the symptoms are improved by the use of the myotics, in conjunction with other medicinal measures, and the eye recovers from the attack, the operation should not be performed until the eye becomes entirely quiet. That it should be performed at this time, both as a preventive and curative measure, has been proved by thousands of cases.

Massage of the eyeball through the closed lids and application of galvanism have their advocates, but the consensus of opinion seems to be in favor of some one of the surgical procedures, and preferably iridectomy.

#### ON THE MANAGEMENT OF PATIENTS WITH TYPHOID FEVER.\*

BY SOLOMON SOLIS COHEN, M.D., PHILADELPHIA,  
Professor of Clinical Medicine and Therapeutics in the Philadelphia Polyclinic; Lecturer on Clinical Medicine in the Jefferson Medical College; Physician to the Philadelphia Hospital; etc.

The title of this brief communication expresses the principal idea it is intended to enforce. In no other disease is it more important to bear in mind that the true function of the physician is not to attempt to interfere with the normal evolution of recovery, or

the processes by which this is brought about, but rather to guide his patient safely through them. Within recent years two series of experiences have impressed upon the profession in America (one from the negative, the other from the positive side) the needed lesson that temperature in itself is not to be feared, and as a symptom is not to be directly combated, save under extreme circumstances. The unfortunate results of treatment by the coal-tar products have practically demonstrated the danger of mere antipyretic dosing; while on the other hand the excellent results obtained by the use of cold water, after the method of Brand and in other ways, have shown that the febrile process expressed by high temperature may readily and safely be controlled within certain limits, to the great increase of the patient's comfort, and with improvement of his chances of recovery.

Although I advocated the Brand system\* and employed it according to my limited facilities before many of its present advocates had seen fit to forego the use of antipyretic drugs, I do not hesitate to place myself on record against the extreme views now expressed in its favor. Of all routine methods of treatment it is the best, but no routine treatment is good. The patient must be taken into consideration; and by this I mean not alone the individual, his temperament and idiosyncrasies, but all surrounding circumstances, and the manner in which he is reacting against the morbid processes, as expressed by all the symptoms of the case.

It is the greatest mistake possible for the physician to look upon all the disturbances of function seen in sickness as in themselves morbid, and requiring to be antagonized.† Many of them are expressions of the natural tendency toward recovery; just as the swaying of the tight-rope walker to left and right is not an evidence of ataxia but of the effort and the ability to preserve his equilibrium. To strike up the arm of the funambulist would cause his fall; and to strike unnecessarily or violently at the temperature, the diarrhea, the cough, of a patient with enteric fever may precipitate him from safety into the grave. The physician, knowing the natural course of the disease, its dangers and its complications, must watch carefully the

\* *Medical and Surgical Reporter*, Philadelphia, June 25, 1887.

† I have discussed this question more fully in an address entitled "Some Thoughts Concerning Disease and Recovery in Their Relation to Therapeutics," *THE THERAPEUTIC GAZETTE*, Sept. 15, 1896.

\* Read before the Medical Society of the State of Pennsylvania, Harrisburg, May 17, 1898.

tendencies exhibited in the individual case, and safeguard his patient accordingly.

Taking for granted that the well-known rules of diet are observed (and as to diet, while there must be the same careful individualization as in other respects, some patients requiring much food and some doing far better with little food, I usually advise small quantities of the most easily absorbable foods—preferably pancreaticized milk or (home-made) expressed beef-juice, administered every second or third hour), and that the hygiene of the sick-room is properly cared for, water, and often cold water, is the one agent of greatest usefulness in the management of patients suffering with enteric fever. It should be used freely in every case, internally as well as externally. Too often nurses unless instructed will wait for the patient to ask before offering him water to drink. This is not good nursing. The patient may be too dull to realize even the sensation of thirst. Nurses should be instructed to give at least a quart of water to drink in the twenty-four hours—boiled water if there be any doubt of its purity. In many cases systematic sponging with cool or cold water will fulfil all the indications for external hydrotherapy. The sponging must be thoroughly and properly done. Nurses must be specifically and carefully instructed in its details. Cold packing, rubbing with ice, and the like, may be used in cases of hyperpyrexia in which the bath is not available; but when available in cases severe from the outset, or which become severe in spite of treatment, the systematic cold bath should be instituted. The inexpert will do better by following the rigorous method of Brand than by attempting to modify it. The experienced will introduce such modifications as each individual case seems to require.

In a ten minutes' paper, and upon a subject so thoroughly discussed, one cannot take up much time in details. Yet success depends upon the care given to little things, and I must here note that many nurses fail to prepare the bed properly for the reception of patients after the cold bath, and it is necessary for the physician to give specific instructions to have heated blankets ready; to receive the patient upon a warm sheet, which is to be tucked in so as to prevent two wetted skin surfaces from coming in contact, and which can be used for drying the patient and should then be removed to permit him to lie between the two warm blankets. The use of red wine rather than

whiskey to give the patient before and after the bath is advisable. In some cases the use of aromatic spirit of ammonia answers the purpose. Between the tenth and twelfth days it is doubtful whether plunging should be begun. After the twelfth day the inexpert should never begin plunging. Plunging begun earlier should be continued or discontinued according to circumstances. When plunging is not well borne, or when for any reason it has not been instituted, frequent cold or cool sponging should be carried out. This is partly to reduce temperature, but largely, like the bathing, to promote general metabolism, to stimulate excretion, and to keep up the tone of the peripheral vessels. Too much stress can hardly be laid upon this latter factor. The effects on temperature, pulse, respiration, excretions, sleep, and general comfort must be the guides as to the time, temperature, and other details of the external application of water, whether by plunging or sponging. Too great a fall of temperature after sponge bath or plunge bath is harmful. The pump-handle charts resembling septic fever shown in some hospital wards where typhoid patients are plunged, are bad charts. They are always too long; they often exhibit unnecessary relapses. A fall of one and a half degrees F., or at the most, of one degree Centigrade, is enough for a single bath. Nor should patients be awakened every two or three hours to have the temperature taken or to be sponged or bathed. They should be allowed to sleep undisturbed, if they can, for four or five hours, even when the applications are being made every second hour during wakefulness. It may be here interpolated that the same caution as to waking the patient for food should be observed.

To reduce temperature, should this be thought necessary, and to prevent or control tympanites or hemorrhage, the continuous application of ice to the abdomen—usually over the right iliac fossa—is useful. Sometimes it is advisable to intermit the use of ice, or to alternate the application of ice to the head and abdomen. In cases of severe nervous and cerebral symptoms or very high temperature there may be continuous application of ice to both head and abdomen. Sometimes an ice-bag over the precordium is conducive to comfort. McCormick has had excellent success with the use of guaiacol externally.

Internal medication is useful. I am positive as to this. The bowels should be

cleansed by enema on admission (unless after the tenth day), after which, according to circumstances, a few small doses or one large dose of mercurous chloride (calomel) should be given. After the "calomel stool" intestinal disinfectants may be usefully employed. These, as I have elsewhere expressed it, may not kill Eberth's bacillus, nor neutralize its toxins, nor chase after it into the spleen or cerebrum; but they do render the patient's intestine a less favorable breeding ground for this organism and its many named and unnamed congeners; they do diminish the formation and hence the absorption of various named and unnamed toxins; they do render the course of the case less severe. I affirm this unhesitatingly as the result of a sufficient clinical study. Laboratory explanations may be found hereafter.

Of drugs of this class no one agent shows so marked a superiority over others as to warrant special claims in its behalf. One may use guaiacol or its combinations, of which I prefer the carbonate; phenyl salicylate (salol), betanaphtol or its benzoyl compound (benzo-naphtol), creosote or its carbonate (cresotal), carbolic acid and iodine, and the like. I usually employ salol or guaiacol carbonate in doses of about five grains every second to fourth hour; more recently I have used benzo-naphtol in doses of ten or fifteen grains. If diarrhea is troublesome, bismuth salicylate may be used in conjunction with the more powerful antiseptic, or beta-naphtol-bismuth (orphenol) may perhaps be equally useful. If constipation be a feature of the case enemata are usually necessary, though calomel in small doses may be used in some instances. When the enema is used it should be repeated, if necessary, every forty-eight hours, except during the period when ulceration is at its height, say from the twelfth to the sixteenth day, when the bowel should be let alone.

If notwithstanding the free use of water the urine is not excreted in sufficient quantity (that is if it be less than 30 ounces in a day) some mild diuretic, as solution of ammonium acetate, or sweet spirit of niter, or infusion of buchu, should be given. This is rarely necessary, as the water drunk is usually an efficient diuretic, and the stimulation of the skin by water and friction in tubbing or sponging likewise assists excretion.

During the second week strychnine is useful in small doses as a mild tonic stimulant. One may give from  $\frac{1}{100}$  grain to  $\frac{1}{80}$  grain every second to sixth hour. The smaller dose is

preferable unless the prostration of the patient be excessive. During the third week the dose of strychnine may be increased to  $\frac{1}{40}$  grain every third hour, if need be. Alcohol is rarely necessary before the third week, and often is unnecessary throughout. It is to be given not as a stimulant, but as a food.

A word as to an old-fashioned remedy may be permitted. When the tongue is dry, harsh, fissured, covered with brownish fur, turpentine is useful beyond doubt. Sufficient must be given to produce an effect upon the intestinal mucous membrane. The usual dose is about 15 drops in emulsion or syrup of acacia, every second to fourth hour. If any sign of renal irritation develop turpentine must be abandoned. I have, however, never seen it do harm, and have seen it do good too often to be laughed out of its use. The occasion for it usually arises during the third week, or during convalescence. It also serves well in cases of tympanites or hemorrhage. In some cases dilute hydrochloric acid serves a good purpose, late or early, according to circumstances, in maintaining digestion and preventing gastro-intestinal fermentation and tympanites. When hemorrhage occurs the quantity of fluid of any kind administered, water or food, must be reduced to the lowest point. Milk must be stopped and beef juice substituted.

Time will not permit of extended reference to complications; to say they are to be met on general principles is to repeat what I have stated to be the main thought of this paper; that good judgment in the individual case, and the use of measures as simple as possible, will give a low typhoid mortality. The objects to be held in view are the patient's rest and comfort; the prevention of nervous symptoms by the prevention of hyperpyrexia and toxemia; the avoidance of rapid fluctuations in the condition of the patient, and especially of such abuse of antipyretic agents or hydrotherapeutic measures as will convert the temperature course from that of a continuous to that of a remittent fever; the sustenance of the patient's strength by judicious feeding, avoiding extremes, and by the judicious use of tonic medication and of agents acting upon the alimentary canal; the maintenance of excretion at a height sufficient to flood out from the tissues the increased products of waste, the peccant humors of the ancients; above all, the strict avoidance of meddlesome interference with necessary processes in the development of the case toward recovery.

### ACCURACY IN THERAPEUTICS.

It is but a few decades ago that physicians, ignorant of the true action of drugs and dependent upon pure empiricism in their uses, were accustomed to prescribe a large number of medicines for each patient with the hope that one or more of them would seek out the difficulty and remove it. This method of the "shot-gun" prescription not only rested upon ignorance of the action of drugs upon living tissues, but far more upon ignorance of the underlying causes of disease and the pathological lesions which resulted therefrom.

Every advance in pathological knowledge finds an accompanying advance in therapeutic procedures for the relief of the affection described, and clear ideas of the conditions present enable the physician to inaugurate a plan of treatment directly applicable to the state before him. This has resulted in the employment of single remedies to produce definite results, and this again has necessitated the preparation and use of medicines so carefully prepared that they can be relied upon to produce an exact effect. As

long as human beings differ one from another in their characteristics the personal equation must be an active factor in medication, but the difficulty of having a similar individual difference in preparations of the same drug is now done away with to a large extent by those manufacturers of medicinal substances who use advanced methods of standardization and take a pride in the accuracy of their finished products. In other words, the time has come when the physician, face to face with a dangerous condition in his patient, should not use products concerning which doubt is possible. It is the hunter's desire when shooting a dangerous animal to use a rifle so accurate and ammunition so reliable that nothing that scientific skill can bring to his aid is lacking, and he must feel that aside from the possibility of error in his own judgment everything he uses must be of the best. So, too, the physician when prescribing should have every confidence that the remedy he is using is reliable and capable of causing a definite effect in a given dose, as by this means he eliminates an uncertainty which may seriously warp his judgment if it is allowed to exist.

At the present time nearly every drug employed in medicine can be so prepared as to be normal in its strength and constant in its effects, so far as its own power is concerned.

When practically all the influence of a remedy rests upon an alkaloid the profession are in the habit of using this alkaloid in place of ordinary galenical preparations, but there are drugs which do not contain a single active principle and others whose active ingredients are difficult of isolation. Still others vary in the quantity of their activities, in different specimens which apparently have the same appearance botanically, to such an extent as to make pharmaceutical products prepared from them very different in their physiological action. The fact must be recalled that a difference in the supply of sunlight and moisture to a plant and variations in temperature and soil make extraordinary differences in the quantity of the active ingredients contained in the crude drug. It is therefore evident that very extraordinary possibilities for variation in effect may exist even in the most carefully prepared fluid extracts and tinctures which can be found upon the druggist's shelf. Those who have followed this matter closely know full well that fluid extracts and other preparations of crude drugs made from a given number of samples apparently identical in character and

by identical processes sometimes vary as much in strength as 100 per cent., and we have already mentioned an instance in these columns in which twenty drops of tincture of nux vomica was almost devoid of any physiological activity, while twenty drops of another tincture was four times as strong in the quantity of strychnine and brucine which it contained; yet in each instance the nux vomica beans from which the tinctures were prepared were in the eyes of competent examiners identical in their appearance and apparently of equally good quality. It is this variation in strength of alkaloids or active principles which is so often responsible for the production of excessive effects in susceptible individuals who have been ordered doses strictly within the line of those commonly employed, while on the other hand innumerable instances can be quoted in the practise of every physician where a drug has been given with the result that no physiological effect has been produced. Ordinarily this excessive action on the one hand, or failure of effect on the other, has been attributed to idiosyncrasy on the part of the patient, when in reality it should have been placed to the credit of the non-standardized galenical preparation. It seems therefore evident that physicians should always employ galenical preparations which contain a definite and known quantity of their active principles, if possible determined by quantitative chemical assay.

But it may be asked what test is to be applied to those drugs whose active principles are not readily analyzed, whose physiological activity depends upon volatile principles, upon glucosides difficult of isolation, or upon constituents which chemistry has as yet been unable to isolate accurately. The answer to such a question is that such remedies should come to the physician's hands having been tested by physiological means. Thus it is well known that ergot contains ingredients which on the one hand have a stimulant effect upon the uterus, while others have an influence upon the blood-vessels; and it is also known that ergot which apparently is the best that the market can provide frequently lacks these ingredients, with the result that the administration of the fluid extract made from such a crude drug is absolutely useless in combating those conditions in which this important drug is so often employed. Not only is this true of ergot, but digitalis, strophanthus and similar important remedies require a physiological

test before the physician can rest assured that a good result will follow their administration.

The paper of Dr. Houghton, which appeared in the July GAZETTE, is an interesting illustration of the benefits of physiological testing as applied to practical medication, and he tells us that recently a well known firm of manufacturing druggists rejected no less than 20,000 pounds of crude ergot, in appearance apparently A No. 1, which failed to produce proper physiological effects when samples of it were physiologically tested. For this reason this 20,000 pounds of ergot was not utilized by that house, yet in all probability the same 20,000 pounds has by this time been put upon the market by other manufacturers who are not in the habit of employing such a test for their crude drugs. Surely no one believes that this 20,000 pounds of ergot was cast into the sea! On the contrary, it has been cast into the stomachs of those unfortunate persons who needing its beneficial effect pay for something which they do not get and perhaps lose their lives through its failure to produce the necessary physiological effect.

The practise of medicine is necessarily surrounded by so many uncertainties which cannot be avoided, and the physician is so often disappointed in the results of his treatment, that it is his duty, as we have said earlier in this article, to eliminate every possibility of doubt in the treatment of his cases both because of humanity and his own personal advancement.

Until each individual member of the profession demands that the materials used in his practise shall be reliable a large amount of avoidable failure in treatment must ensue. What artist in his endeavor to make a reputation would use cheap colors or poor brushes? What surgeon would permit any doubt as to quality to rest upon the instruments which he employs in the performance of a delicate operation? and yet how many physicians face to face with desperate conditions daily employ drugs concerning which there is no certainty as to their action!

---

#### *THE TREATMENT OF PURULENT PERICARDITIS.*

---

The treatment of pericarditis with effusion has been discussed several times in the pages of the THERAPEUTIC GAZETTE during the years 1897 and 1898. In connection with

these articles a paper which has appeared in *The Lancet* of April 23, 1898, by Sevestre, is of considerable interest. His patient was a man of twenty-two years, who came under observation at the Addinbrookes Hospital in Cambridge, England, and who passed through a long illness which ultimately ended in his death. Although the symptoms of a pericarditis with effusion were not distinct, and although there were evidences, also, of there being a double empyema, an exploring needle was passed into the chest in the neighborhood of the heart and a syringe of pus was withdrawn, this operation being followed by great relief. The patient, however, once more became dyspneic and apparently exceedingly ill, and upon the needle of the aspirator being passed into the pericardium twenty-three ounces of sweet, creamy pus were withdrawn, which proved to be almost a pure culture of the pneumococcus. The patient at once became markedly improved in his general condition, but once more relapsed after the lapse of a few days, so that finally a wound was made in the fourth interspace, and the director being pushed into the pericardium pus once more escaped. Later on an inch of the ninth rib posteriorly was excised and a large quantity of pus escaped from the chest wall on both sides, so that he speedily drained purulent material constantly from all three openings.

The value of Sevestre's paper, however, consists of the useful summary of cases of pericarditis which have been treated by operation, in all amounting to seventeen. In a number of instances the purulent pericarditis seemed to arise from the infection due to the pneumonia which ensued. In other instances he believes that it has arisen from the spread of the inflammatory process in the mediastinal glands, particularly where the mediastinal disease has been tubercular; and, further, he asserts that as the results of his studies it is by no means uncommon to find that the pleural cavities are involved, as they were in the case under his own observation. It is, however, of interest to note that in some of these cases the pleural effusion was serous, while that in the pericardium was purulent.

In discussing the locality in which a paracentesis pericardii should be performed, Sevestre points out that there is still a considerable difference of opinion, but believes in the majority of instances the fourth or fifth interspace on the left side of the sternum is the point of election. He also notes the fact that Rotch has advocated doing the

operation on the right side in the fifth interspace, but does not himself look with favor upon this proposition. Where the purulent pericarditis eventually points and finds an escape for itself, it is interesting to note that in one instance an abscess formed over the ensiform cartilage and was found post mortem to be connected by a sinus with the pericardium. In one instance the pus burrowed forward and down in the second left interspace close to the sternum. Finally Sevestre reminds us of the fact that Rosenstein with Leyden deserves the credit for being the first to incise and drain the pericardium, the patient entirely recovering.

Out of the seventeen cases tabulated by Sevestre, six are reported to have recovered; and, finally, it is evident from the statistics that incision of the pericardium has now been done a sufficient number of times to make it clear that it is not very difficult or dangerous, and it is certainly the operation to be performed when the otherwise hopeless character of the condition is recognized.

#### THE INFLUENCE OF QUININE IN LABOR.

THE THERAPEUTIC GAZETTE during the past year has contained several items in regard to this question. In one of these a German authority claimed that quinine was a useful oxytocic. On the other hand, an original article contributed to the columns of the THERAPEUTIC GAZETTE by its editor, with the title of "The Value of Quinine as an Oxytocic," contained a large number of opinions derived from expert obstetricians showing that quinine did not possess marked oxytocic properties, and in one or two instances it was claimed that it was distinctly deleterious in its influence during parturition. In this connection, therefore, a recent paper by Dr. L. J. Hammond, of Philadelphia, read before the Philadelphia Obstetrical Society, and published in the *American Gynecological and Obstetrical Journal* for April, 1898, is of considerable interest. His paper is based upon one hundred cases of labor in which quinine was employed, the majority of the observations being made by advanced medical students under his direction.

Both primiparas and multiparas were used. In the case of the latter, an effort was made to determine the character and duration of the previous labors, but it was found to be so unsatisfactory that it was abandoned. The number of primiparas was thirty-eight, multiparas sixty-two.

There were never less than five nor more than seven observations recorded except in two or three cases, where four were made, owing to the rapidity of the termination of labor, and as so large an amount of time would be consumed in detailing these half-hour observations, the author has endeavored to summarize sufficiently to make clear the results of the investigations without too greatly wearing upon our patience, and with this object in view has endeavored to take the maximum number of seconds and the minimum number of seconds and the maximum minutes of interval and the minimum minutes of interval before the drug was given, and compare them with the maximum number of seconds and the minimum number of seconds and the maximum minutes of interval and the minimum minutes of interval after the drug was given. Usually from three to five observations were made before administration of the drug, no observation being made during the very last moments while the head was passing through the vulva.

The study of the action of the uterus after being emptied of its product of conception was to note, first, whether there was any excess of bleeding; second, whether firm contraction immediately occurred after it was emptied; third, whether any condition of hour-glass contraction took place.

As the report shows, but five evinced any tendency to excessive bleeding, and in no case was there any contraction of the lower segment noted. In all the rest the uterus promptly and permanently retracted after prompt expulsion of the placenta.

In but one of the cases was the temperature, pulse or respiration sufficiently disturbed from the normal course to be noteworthy, and that was in the third case in his table, which shows a pulse of 110, respirations slow (12), and temperature normal.

It is to be seen from the tabulated report of Dr. Hammond of the thirty-eight primiparas, thirty-five show an increase in the frequency of contractions after the administration of the drug, two show a decrease, and one no change.

We find upon further examination of the table that eight of these cases showed increase not exceeding one minute; therefore it will be fair to state that there was decided change in twenty-seven.

As to the duration of contraction, we find, of the thirty-eight primiparas, one decreased and two show no change. Of the sixty-two

multiparas, four show an increase in the interval between the contractions and but one shows no change, while twenty-seven show that the increase in the frequency of contractions did not exceed one minute. On the other hand, a study of the duration of the contractions shows that four of the sixty-two cases show a diminution in the duration of the contractions after the use of the drug, and in two no change was noted.

In comparing the frequency of contractions in multiparas with those of primiparas, we find that the interval between contractions is slightly longer in the former than in the latter, while on the whole the duration of contractions in multiparas is longer than that of the primiparas.

These observations were made on women living in courts and alleys, mostly in the extreme lower section of the city, where the sanitary conditions, as well as the foodstuffs used, were far below what is necessary for the safety and comforts of life. The district is said to be the most malarious in the city, and taken all in all, the writer believes this class of women to be an ideal one for securing the best results from any therapeutic agent whose benefits are supposed to be produced by its action as a tonic.

There is great difficulty in determining just what amount of the increase both in the duration and frequency of contractions that are noted in these observations is due to the action of quinine; first, because it is well known that as the second stage of labor progresses the interval between contractions is diminished, as well as the duration of the contractions increased. The prompt increase, however, in the duration of contraction and the diminution of the interval between contractions, which is so uniformly shown to have occurred in his series of cases, and in the hands of twenty-five different observers, would seem to justify the belief that this drug does exercise a marked influence on the expulsive powers of the uterus; and the writer is satisfied that, given a woman whose muscular system is below par and an atonic condition of all the muscular structures of the body, he believes the administration of quinine, begun in the early stage of labor, will not only increase the expulsive powers of the uterus by its general tonic action, but it will also, through this same action, tend greatly toward lessening the dangers of septic invasion, which this class of cases is particularly liable to, owing to this impoverished condition of the system. In other

words, it has been the writer's experience to find that uterine inertia, which is said by some to be so common, is extremely rare, and is found only in the class of cases that he has here described. From a large experience, both in this class and a better class of cases, he is convinced that the so-called uterine inertia does not exist in any other class of cases than that where all the other muscles are tired, or, more properly defined, where there is general muscular atony, and he thinks quinine is useful in labor.

#### A BLUNDER OR A CRIME.

---

"It is worse than a crime, it is a blunder."

—TALLEYRAND.

Those of us who are fond of history and literature will remember that Madame Roland as she was about to die exclaimed, "O, Liberty, Liberty, how many crimes are committed in thy name!" and we feel as if in these days it would be well to paraphrase this sentence by the substitution of the word *Science* for Liberty, for it is a fact that Behring and his agents have applied for and received patents which are designed to give him sole control of the manufacture of the antitoxin of diphtheria. For years the original investigators of the German laboratories have deserved and received the admiration and respect of the scientific world because of their devotion to science for its own sake. For years the great teaching institutions of the world have sent their best young men to the German universities in order that they might receive that spirit of scientific ardor which, like the touch of the king's sword, raised the servitor to knighthood, and this self-sacrificing spirit was perhaps the most important part of the benefit of a foreign trip. The rank commercialism of the present day has, however, entered those institutions of learning which have heretofore been above reproach, and we find that Behring's scientific reputation is to be shadowed by venality and greed.

This, however, is the least important part of this subject, and the scientific investigations of other equally reliable, and more ethical, men, which have led to the possibility of Behring's work, are to be used as stepping-stones for his benefit. Far more important is the question as to what influence the success of this application for a patent will have upon the lives of many hundreds of patients in the course of every year. Had

equal commercialism governed Jenner, how many thousands of individuals would have died of smallpox, and what would have been the effect upon the universal limitation of the disease to-day had such an ethical error been perpetrated? Even though the life of the patent would have lasted but a few years, incalculable harm would have ensued.

So far it has been taken for granted, in part at least, that Behring has a legal right to this product. This is not the case. Others had utilized the same principle years before he did so, and the literature of medicine teems with the papers of those who are in great part his leaders in the discovery of diphtheria antitoxin. Nor is this all, for his rights are so uncertain that other governments will not issue protective papers to his monopoly, and only our lax American laws permit him to obtain a patent.

There are times when the physician must, like our New England forefathers, leave the ploughshare of practise for the fight, and this is one of them, for it is a struggle of the rich and the poor against a terrible scourge and a strong monopoly, and the voice of the medical profession should be raised in no uncertain tone against this outrageous instance of grasping greed. Such greed often overreaches itself, and the profession should remember that the Höchst Farbwerke, formerly Meister, Lucius & Brünig, who are the active agents in this matter, are dependent in large degree upon the favor of physicians. "To what base uses have we come at last" if we can be used by such persons as the tools by which their dividends are paid? And are we as citizens of this great country and members of an equally great profession to sit quietly by while our scientific birthright is taken from us? *Caveat emptor*, let the buyer beware, of those who seek to practise the imposition.

---

#### THE IMPORTANCE OF OUR FOREIGN LETTERS.

---

This issue of the THERAPEUTIC GAZETTE contains two foreign letters in particular, namely, those from Berlin and Paris, which illustrate an important function of the THERAPEUTIC GAZETTE in disseminating information in regard to the best treatment of disease. The Berlin letter records in an interesting way the opinions of Professor Koch as a result of his study of infectious diseases during his recent visit to Africa, and we are

particularly interested in his assertion that in a large number of instances the excessive use of quinine is responsible for the development of black-water fever, or malarial hematuria. This is a matter with which the readers of the GAZETTE are already familiar, for during the seven years in which the present editor has had charge of its columns a number of important original, editorial, and progress items have been published on this subject. These statements of Koch's, coming from such a high authority, are worthy of much attention; but it will be remembered that many Grecian and other physicians on the other side of the Atlantic have long held to this view, and that in the collective investigation of malarial hematuria made by the editor of the GAZETTE a few years ago similar conclusions were discussed. Another important point in this letter is the question of the administration of large quantities of mercurials in the treatment of advanced nervous lesions of old syphilis. We are speedily learning that drugs that are powerful for good when properly used are also powerful for harm. Much interest also attaches to the *résumé* of the views of Laugen-hagen, of Cannes, concerning the treatment of muco-membranous enteritis, which will be found in the Paris letter.

The Correspondence department is maintained under a large expenditure, but we think the information obtained by our readers from these letters is a valuable addition to the GAZETTE, which is and should be universally appreciated.

---

#### TUBERCULOSIS OF THE TESTICLE.

---

Tuberculosis of the testicle does not, at least in current journalism, receive the attention which its comparative frequency, its diagnostic obscurity in its early and most amenable stages, and its important bearing on the general health would seem to warrant. The etiology, pathology, prognosis and treatment of the affection still remain to be settled, and certainly the experience of every surgeon is to the effect that the disease is usually well advanced before special treatment is sought.

The means by which the tubercular infection reaches the testicle are of course those by which the bacilli are carried to any point of the body. From the mass of clinical evidence it seems clear that this infection is usually a descending one from the prostate, that tuberculous epididymitis and orchitis

are commonly complicated by latent or active prostatitis—often by infection of the bladder and kidneys, sometimes by tubercular lesion in remote parts of the body—and that in a fair proportion of cases the affection is an absolutely local one, the other organs being healthy. It may develop at any age, records having been published of infants and octogenarians being afflicted with this disease, but it is commonest at the period of lustiest life—*i.e.*, early manhood.

The normal testicle has toward the tubercle bacillus marked resistant powers, if Jacks' observations can be trusted. These are to the effect that a tuberculous patient may secrete through a healthy testicle semen containing virulent tubercle bacilli. The favoring condition for the lodgment and growth of these bacilli is lessened resistance usually incident to gonorrheal inflammation, trauma, or physiological congestion. The latter is a factor of very great importance. The affection is commonly bilateral (seventy-five per cent.), but rarely so synchronously. The disease may remain in one testis or epididymis for weeks or months before the other becomes affected. Under such circumstances it is possible that the prostatic affection may be secondary to that of the testicle, but more probable that it was primary. The onset of the disease is sometimes as sudden and violent as is that of a gonorrheal epididymitis. The partial subsidence is rapid in these cases. As a rule the onset is insidious, and with inflammatory symptoms or only slight ones; nodulations form in the epididymis, often about its upper portion first, but frequently in exactly the position characteristic of the induration following gonorrheal inflammation.

Preceding or accompanying these insidious cases there is often observed a slight intermittent gleet discharge, some frequency in urination, blood at the end of micturition, pus in the urine; a rectal examination will often show nodulation of the seminal vesicle or the prostate of the affected side. This slight gleet leads to error in diagnosis, the physician taking it for granted that a urethral discharge is necessarily of venereal origin. The nodulation in the epididymis may be the only sign of the affection, the genito-urinary tract remaining clean and the urine showing nothing abnormal on repeated examination. This is not commonly a reason for the conflicting views expressed as to the treatment appropriate to tuberculosis of the testes, and is to be found in the fact that

the disease exhibits a marked tendency to remain localized for a long period. There are many spontaneous cures reported. Tubercular involvement of any portion of the genito-urinary tract is commonly slow in its development. If the affection were invariably rapid, progressive, and as a rule became disseminated, the advisability of early extirpation would so generally be recognized that but few words would have to be said as to treatment. As it is, the majority of surgeons advocate immediate partial or complete castration as soon as the diagnosis of tuberculosis of the testicle is clearly established. Theoretically this seems objectionable, because of the apparently well established fact that the involvement of the testicle is generally secondary to foci of disease in the prostate, and that unless a vasectomy and prostatectomy are performed in addition to removing the testes the patient is ultimately not likely to be benefited. As a matter of clinical experience, however, it has been shown repeatedly that after removal of a diseased testis and cord the infiltration distinctly perceptible on rectal palpation has subsided and a permanent cure has been accomplished. R. Koenig reports many such cases.

There is, however, a natural hesitation in advising even a unilateral castration when there is even a hope of saving the organ, a hesitation which unfortunately does not obtain in the consideration of the affections of the ovary. Moreover, men are exceedingly reluctant to have this operation performed, and if they can be told that even a small percentage of cases recover without it, are prone to take these chances.

The statistics of tubercular epididymitis and orchitis treated by non-operative means remain to be taken, but it is noteworthy that a surgeon as experienced and modern as Guyon counsels many of his patients to adopt those hygienic and climatic measures which have yielded such good results in pulmonary consumption and which have given him a large percentage of apparent cures.

The advantages proven for operation are: That it at once removes a focus of infection and of possible dissemination, and this by a simple and safe procedure; that it removes an organ the physiological activity of which is already destroyed; that it exerts a distinctly modifying effect upon tuberculous infection of the prostate and tubercular cystitis; that in the distinctly localized cases it is absolutely curative. All these advantages seem to be shared by thorough removal of the

tuberculous foci, leaving as much of the testicle as seems healthy. When the disease is bilateral this procedure would seem particularly to be indicated, because of the systemic influence of testicular tissues and because of the excellent results following it. The method is one which is steadily growing in favor.

When a tuberculous testis first comes under observation the first thought should not be to suggest operation. The effect of pressure, elevation and moist heat should first be tried. This is best applied by a shallow suspensory bandage made of mackintosh and gored at the sides and provided with lacings. The testicles are covered in by a layer of absorbent cotton, the suspensory is applied, drawn well up by the perineal shape and finally laced at the sides. The patient should at the same time be placed under the most favorable hygienic conditions. If the disease is progressive the infiltrated foci should be removed with the curette or knife; if the major part of the testes is involved complete castration is indicated, even though there be evidences of prostatic, vesical, or renal involvement. It is worthy of note that even patients presenting all the cardinal symptoms of renal tuberculosis may recover.

---

## Reports on Therapeutic Progress

---

### *PULMONARY EMBOLISM FOLLOWING MERCURIAL INJECTIONS.*

According to EPSTEIN the treatment of syphilis by injections of insoluble mercurial preparations presents, in a large number of cases, an incontestable superiority over other methods, and the practise should not be renounced unless the complications on the part of the lungs produced by embolism are frequent and grave.

From 1892 to 1896, under the direction of Dr. Jadassohn, in Breslau, 227 men and 681 women were treated with injections of insoluble mercurial preparations. In all, 8292 injections were made, ordinarily with thymol, mercury acetate, or mercury salicylate in liquid paraffin. Among these patients embolisms were ascertained as follows: In 1752 injections in men; in 1090 injections in women; and in 1185 injections in persons of both sexes.

No deaths occurred in the cases of embolism; furthermore, all the patients were cured in a short time. The author does not concur in the opinion lately expressed several times

in favor of rejecting injections of insoluble mercurial salts solely because they may accidentally give rise to pulmonary embolism. He is, in this respect, in complete accord with the majority, not only of German physicians, but of other physicians.

According to Möller, the following rules should be carried out in order to avoid an injection into a vein and consequent pulmonary embolism: At first, the mass to be injected should be deposited in the gluteal region and as deep as possible, so that the injection is made above the muscles or in the superficial part of the gluteus. The upper gluteal region, above the horizontal line which touches the upper part of the great trochanter, presents the least danger from embolism. Möller seizes a thick fold of the skin and of the subcutaneous tissue parallel with the median line and introduces the cannula (which should be at least three and a half centimeters long) for its entire length, following an oblique line in the direction of the fold of the skin and deep into the skin and the subcutaneous tissue in order that the injection may stop short of the muscle, or at least touch only the superficial part of it.—*New York Medical Journal.*

#### REPORT ON THE PROGRESS OF SERUM THERAPY IN GENERAL—IN VIRGINIA ESPECIALLY.

A committee of the Richmond Academy of Medicine and Surgery reports in the *Virginia Medical Monthly* of February 11, 1898, its conclusions in regard to this subject. An exhaustive report concludes as follows:

Antitoxin is the most valuable remedy yet devised in the treatment of diphtheria.

Its use is especially valuable in laryngeal cases.

It should be employed at the earliest possible moment after a diagnosis is made.

The initial dose should be (according to the type and severity of the case) from 1000 to 3000 units of a concentrated serum, and should be repeated according to indications.

Local and other general treatment should not be neglected because antitoxin is used.

As a prophylactic agent its value is unquestioned.

#### INHALATIONS OF VINEGAR TO CONTROL NAUSEA AND VOMITING AFTER ANESTHESIA.

The *Philadelphia Polyclinic* of February 26, 1898, contains an article on this subject by Dr. J. T. RUGH in which he tells us that

many and varied are the methods proposed and used to overcome this disagreeable and frequently serious symptom, but all have proved only partially successful. In one of the Boston hospitals the injection of atropine prior to beginning the anesthetic was followed very carefully and for a long time on the principle that it would stimulate the inhibitory vomiting center which was supposed to be paralyzed during complete anesthesia, which fact may be but one of the causes acting rather infrequently, but its use was only partially successful. The combination of morphine and atropine has been used but has not been found satisfactory. Bromide, chloral and other antispasmodics have also been administered with a varying degree of success.

One of the simplest and most satisfactory methods of controlling this condition has been the administration of strong vinegar by inhalation. The use of vinegar in this manner for vomiting was first proposed in 1829 and was practised from time to time by various surgeons, but it remained for Mackenrodt to apply it extensively for vomiting following anesthesia, he probably having adopted it from the recommendations of earlier surgeons who lived in both the pre- and post-anesthetic days. Its beneficent action is explained by Lewin as due to the neutralization of the free chlorine, one of the products of chloroform, by the acetic acid. The chlorine acts as a marked irritant to the pharyngeal mucous membrane and induces vomiting, but it is neutralized by the acid, which soothes the irritated parts as well. Ether, however, is much more directly irritating to the respiratory passages during inhalation, but the vinegar gives as satisfactory results after it as after chloroform narcosis. The simplest explanation of its good effects is that its pungency stimulates—it being too dilute to exert any irritative action—the respiratory mucous membrane, promotes the normal secretions and, by its soothing action upon the peripheral nerves of the parts, lessens the irritability of the pneumogastric or its centers, and the reflex condition of vomiting is controlled. Furthermore, that vinegar is a restorative and soothing stimulant to the respiratory tract and to the nervous system is well attested by its wide-spread use among the ladies in their vinaigrettes in place of "smelling salts." In certain countries the pungent qualities of the aromatic vinegar are used almost to the exclusion of the ammonia or lavender salts, and all be-

cause of the more refreshing effects following its use.

Whatever the correct explanation may be, certain it is that, in cases which have been properly prepared for operation and whose stomachs have not been filled with blood during the operation, it almost, if not completely, prevents vomiting. The method of administration is by saturating a towel or cloth with fresh, strong vinegar (preferably that made from cider), and holding it a few inches above the patient's face, or hanging it from the bedstead, so that it will be near his head. It should be used directly after the anesthetic has been discontinued, and kept up continuously for hours.

In one case, to which ether had been given, nausea began soon, but ceased in about one and a half minutes after using the vinegar. This was then removed, and the nausea returned, but again disappeared after the vinegar was given. The action was so marked that the process was repeated five or six times so as to verify the conclusions, and each time the result was the same as at first noted, the patient quickly becoming quiet as though going under complete anesthesia.

Another case was given chloroform for the removal of pharyngeal growths and swallowed considerable blood. Vomiting of the clotted blood occurred, but ceased immediately after, and did not return.

These have been duplicated by about twenty-five cases, in whom the action was almost uniformly beneficial. The relief from thirst to the patient is most marked, and the refreshing effect is both grateful and welcome to the sufferer. Its simplicity and efficiency commend its use to all having aught to do with such cases. It is also free from any toxic effects, and can occasion no harmful conditions.

**FOR WHAT PERIOD OF TIME CAN IMMUNITY FROM DIPHTHERIA BE CONFERRED BY A SINGLE INJECTION OF ANTITOXIN?—THE DOSAGE.**

This question is asked and answered as follows by MORRILL in the *Boston Medical and Surgical Journal* of March 3, 1898. From actual experience he states that we are perfectly justified in believing:

That immunity in any given case, of no matter how thorough exposure to diphtheria, may be conferred, for at least ten days, by the injection of a small dose (100 to 250 units) of serum, provided it is given twenty-four hours previous to actual infection.

That a larger dose (250 units for a child of two, up to 500 units for one of eight or over) will confer safety for three weeks—or to be a little more conservative, for twenty days—under similar conditions.

That no harm will result from the treatment in a vast majority of cases of sick children, and probably in no case of a healthy child, provided the serum used is up to the present standard of purity.

In conclusion any one who thinks that antitoxin will prevent the occurrence of a follicular tonsillitis or of a coryza in an individual who happens to have the Klebs-Loeffler bacillus in his throat or nose will be disappointed, for neither of these conditions constitutes a diphtheria any more than the coexistence of the pneumococcus in the saliva or a bronchitis constitutes a frank pneumonia. A physician who fails to promptly immunize the members of a family or close community in which diphtheria breaks out, neglects to do his duty by those whose safety lies in his hands.

**CANCER OF THE SKIN.**

Dr. GOTTHEIL writes on the treatment of this state in the *International Journal of Surgery* for March, 1898. He says that among the arsenical pastes are those of Cosme, Esmarch, and Bougard. Cosme's paste, as modified by Hebra, consists of:

- ℞ Acid. arsenosi, 1 part;  
Hydrarg. sulphuret. rub., 5 parts;  
Ungt. aqua rosæ, 40 parts.

It is applied like that of Marsden, but, being weaker, should be removed every twenty-four hours, the parts washed, and the paste reapplied. This formula is not as desirable as that of Marsden. Its weakness causes danger of its absorption, and it does not produce the requisite inflammatory reaction.

Esmarch recommends the following paste:

- ℞ Acid. arsenosi, 1 part;  
Morph. sulphat., 1 part;  
Calomel, 8 parts;  
Pulv. acaciæ, 48 parts.

It is open to the same objections as the paste of Cosme, and is but little used in this country.

Bougard's paste is active enough, but it must be used with caution, as it is liable to destroy the healthy as well as the pathological tissue. Its formula is as follows:

- ℞ Hydrarg. chlor. corros., 1 part;  
Acid. arsenosi, 2 parts;  
Hydrarg. sulphuret. rubr.,  
Ammon. chloridi, of each 10 parts;  
Farini trit.,  
Amyli,  
Zinci chlorid. cryst., of each 120 parts.

The various ingredients should be powdered separately, mixed in a mortar, and poured into the solution of chloride of zinc with rapid stirring to prevent lumping. The paste is applied on a cloth immediately after the preliminary curetting, and is allowed to remain on for twenty-four hours. The poulticing and after-treatment is similar to that after Marsden's paste.

A mixture of arsenous acid with alcohol and water has been used with great success by Czerny and Trunecek. The formula is as follows:

- ℞ Acid. arsenosi, 1 part;  
Spts. vini rect.,  
Aque destill., of each 75 parts.

After a preliminary curetting, or at least a thorough cleansing of the surface of the ulcer, the arsenical mixture, well shaken, is spread over it with a brush. It is allowed to dry on and the part is left without any dressing. Next day the ulcer is found covered with a scab. Every day a new layer of the application is painted on, and the crust, gradually thickening, slowly changes in color from yellow through brown to black. The strength of the solution should be gradually increased during the later applications, until the proportion of arsenic in the mixture is 1 to 100 or even 1 to 80. The scab, composed of necrotic cancerous tissue, gradually becomes detached by suppuration, and can finally be removed. The arsenical mixture is again applied and the result watched. If a thin, easily detachable, yellow pellicle only is formed, it is claimed that the cancerous matter is all destroyed and the ulcer will heal up. If, however, a dark colored, tough and firmly adherent crust appears, the reverse is the case, and the entire course of treatment must be repeated.

Treatment lasts from four weeks to three months. Objections to the method are the length of time required, and the fact that daily applications are necessary. Advantages are its comparative painlessness, the possibility of treating large areas of cancerous tissue at once, and more especially its applicability to carcinomata of the skin involving the mucosæ, or situated upon the mucous membranes themselves. Its authors claim that the treatment does not affect the organism even when employed in the mouth.

Finally, Hue has used arsenous acid hypodermically, employing the following formula:

- ℞ Acid. arsenosi, 1 part;  
Cocain. hydrochlor., 5 parts;  
Aque destil. bulliens, 500 parts.

Several cubic centimeters are to be injected every three or four days into the cancerous tissue; it is claimed that the operation is not painful. Though his recoveries were only called "relative," and his cases all inoperable ones, the hypodermic injection of arsenous acid may be found useful in cases of cancer situated upon the mucous surfaces or in localities where the applications above mentioned cannot be used.

Cutaneous carcinoma is preferably treated, in the great majority of cases, by caustics, which give the best results with the least liability to return.

Excision is to be reserved for those exceptional cases in which, from location or extent, the caustic treatment is inapplicable.

Arsenous acid is the safest, surest and best of the caustics at our disposal, and seems to have a specific selective action upon the cells of the new growth. Pyrogallol may be employed in the most superficial cases.

In cases involving the skin alone, arsenic should be used, after curetting, in the form of Marsden's paste.

Where the mucosæ are also or solely affected, arsenic can be used by the method of interstitial injection of Hue, or as a paint, as recommended by Czerny and Trunecek. The galvanocaustic point, the caustic potash stick and the chloride of zinc may also be employed.

Cutaneous carcinoma, early and vigorously treated by the caustic method, is a very manageable disease, and of good prognosis.

#### COMPARATIVE TREATMENT OF DIPHTHERIA; CASES IN PRACTISE.

KILLINGSWORTH in the *Western Medical Review* of March 15, 1898, tells us that he visited with Dr. Von Grimm, when in New York City, twelve cases of diphtheria, of different severity. Once a day they were all treated with antitoxin, and not a death occurred when the antitoxin was used in the first twelve hours of the disease. There was a characteristic rash that appeared in four per cent. of the cases that he has treated and seen treated. He thinks the rash is due to the horse serum, and not to the antitoxin. Antitoxin does not prevent albuminuria if not administered in the first six hours of the disease, and the paralysis appears after the antitoxin seems to have cured the diphtheria. Aside from these unfavorable complications in the late administration, antitoxin holds second place only to vaccination for prevent-

ing smallpox. Statistics in the greatest number of cases and from the most different sources have proven its worth, for nearly four years' employment of antitoxin in diphtheria has resulted in the saving of thousands of lives. Every claim that has been put forward for antitoxin has stood the test. Results from this treatment have been published by the hundreds. The testimony has been from the best men and of such high standing that the results can no longer be called into question by any one. It is simply the imperative duty of every physician to use the serum early in every case of diphtheria. The author says if he did not see a case early, say in the first twelve hours, he would use the antitoxin with the spray of chloral hydrate, potassium permanganate, and hydrochloric acid, with internal treatment as was indicated in each case.

#### *PRACTICAL MEASURES IN OBSTETRICAL EMERGENCIES.*

MARX in the *New York Medical Journal* of February 5, 1898, says that many men speak of frequent post-partum hemorrhages. He thinks these either denote faulty technique on their part, or else they call every bleeding a true post-partum hemorrhage. He speaks of these hemorrhages as those where in a few moments from perfect health, in good spirits, the woman lies cold, collapsed, gasping for breath, with sighing, yawning, and all those symptoms which we all recognize too well as soul-stirring and marrow-freezing. There may be no external hemorrhage, but the large, relaxed, boggy uterus tells the story but too well. Quick, precise action is required. No theoretical measures are to be thought of. Means that have stood the test of time must be used, and used at once, to bring on firm and good uterine contraction. The writer has thrown aside everything but one of two measures. He countenances but one hot intra-uterine douche, and if this procedure does not bring about the desired result, he does not use irrelevant and dangerous measures, such as direct compression, ice, persulphate of iron, lemon, vinegar, etc., *ad infinitum*, but proceeds to pack the uterus with gauze, toweling, or anything he has on hand. He never goes to a case without five yards of gauze being on hand. This is a surgical means of controlling hemorrhage. The technique of gauze tamponade is simple: one hand over the uterus, while with the other the gauze is shoved in, as it were, until no more can be introduced. So

long as this gauze remains, bleeding cannot occur, for it acts mechanically in controlling the bleeding and actively stimulates the uterus to contraction.

The after-treatment is simple: Postural treatment and stimulation by the needle, with large doses of strychnine given at short intervals; infusion of a saline solution, for the heart needs a fluid, not necessarily blood, to act upon. Intravenous transfusion is difficult of application in those cases, for the veins are so small, so collapsed, that to find them is not only difficult, but valuable time is lost. Hypodermoclysis is all right if the needle and Davidson syringe are at hand, when a pint may be injected under each breast. But we have in the colon an avenue which greedily absorbs about all the fluid we can inject. The tube of a fountain syringe is slowly wormed two feet into the bowel and the salt water allowed to run in, at the same time elevating the buttocks to allow the force of gravity to act in getting in the fluid higher and higher. It is remarkable how much fluid a colon will absorb under these conditions, and how little is expelled. The author had one case where one pint was injected every hour for twenty-four hours with most brilliant results. The water should be hot, and it would not be amiss to add to the salt solution strong coffee, or liberal doses of cognac or whiskey. Ergot is of little value in these cases when given by mouth, for Hemmeter has shown that it takes at least a quarter of an hour to act. As an adjuvant, ergot (or "ergot aseptic") might be given hypodermically, but deep into the outer side of the thigh.

Hemorrhage from the cervix, while not so fatal in its immediate action, can in a relatively short time exsanguinate a patient. Its causes and prophylaxis do not enter into discussion in this paper. The diagnosis is simple enough, if in the presence of a well contracted uterus hemorrhage from the vagina and vulva can be excluded. Its treatment is self-evident, but by what means? Powerful traction from below by bullet forceps or pressure from above, both causing an artificial prolapse of the organ, has in his hands, by putting the uterine arteries on the stretch, caused a cessation of the hemorrhage. Direct pressure for ten minutes, the thumb and index-finger of one hand directly grasping the angle of the tear, has answered in others; or, to the same end, clamps inserted well above the angle of laceration. Further surgical measures would be the firm utero-

vaginal tamponade. These are the varieties of treatment when direct suture and needle are not on hand. The writer only advocates primary trachelorrhaphy in the presence of hemorrhage, and not, as many have advocated, in all cases of laceration. The universal application of sutures is condemned for the reason that if the accoucheur has been surgically clean deep tears will in the largest number of cases heal spontaneously. If the rent is sewed up and strict cleanliness is not observed, sepsis will arise and union not occur. The author speaks of a case where the physician sewed so thoroughly that the entire uterine canal was closed and not a drop of lochia could escape. But in the presence of cervical hemorrhage we recognize the only condition for the primary operation. In itself the operation is simple. Place the woman on the back, artificially prolapsing the uterus by direct pressure, or pulling down the cervix to and through the vulva—in other words, delivering the cervix into the world—passing as many sutures as are required, and tying them tightly; for, since we are operating upon a uterus which will rapidly involute, in which the parts are congested and swollen, bleeding might occur or the wound gape from ligatures that in this wise become loose from not being tied tightly enough.

Following this technique, it is as easy to sew up a rent cervix as it is to operate upon the peritoneum. Hemorrhage from the vagina is rare, and requires simple suturing. Spouting from the clitoris, while apparently a simple matter to treat, is one which has puzzled the writer in finding the source of the hemorrhage. Direct pressure, or a suture passed beneath the bleeding vessel, will readily control the condition.

#### TREATMENT OF TABES.

EULENBURG (*Deutsche Medicinische Wochenschrift*, Oct. 28, 1897) first refers to the new conception of tabes as a disease of the sensory neuron. At first the treatment of tabes was looked upon as useless. As regards prognosis each case must be individualized. Besides pursuing at one time a more rapid and at another time a slower course, the disease may become stationary even in its earlier stages, so that a relative recovery may be spoken of. This arrest of the disease may give rise to error in estimating the value of a given treatment. Nothing is expected nowadays from derivative and

revulsive measures, and the same may be said of the silver treatment. The improvement that may take place under treatment by electricity, by baths, and by the local application of heat or cold, cannot be satisfactorily explained. The value of antisyphilitic treatment is difficult to estimate. The author agrees that a large percentage of sufferers from tabes have previously had syphilis, but syphilis is not the sole or essential cause of the disease. Thus antisyphilitic treatment cannot be described as a radical treatment. Relative recovery is not more common under antisyphilitic treatment than under other methods. Cases of tabes with previous syphilis may improve with or without antisyphilitic treatment. Harm may sometimes be done by injudicious antisyphilitic treatment. Eulenburg emphasizes the value of morphine and strychnine under certain circumstances in this disease. Potassic iodide, antipyrin, antifebrin, etc., are of uncertain value in the pains of locomotor ataxia. As regards so-called organotherapy, treatment by spinal cord extract and by Brown-Sequard's fluid has been tried. The author says that he has used spermin in subcutaneous injection in bad cases with considerable improvement. Nerve stretching ought never to be resorted to. Suspension, etc., may produce improvement, especially in the ataxia. The author speaks highly of Frenkel's treatment of ataxia by compensatory exercises. Thus the ability to work may be preserved or even recovered. The question of sending patients to health resorts is next discussed; it must, of course, largely depend on the means of the patient.—*British Medical Journal*, Feb. 26, 1898.

#### PICRIC ACID IN ECZEMA.

AUBERT (*Thèse de Paris*, No. 32, 1897) says that speaking generally picric acid is indicated in those forms of eczema in which the inflammation is acute and superficial, and where the lesions are mostly epidemic. The keratoplastic action of the remedy cannot display itself in the chronic forms of eczema accompanied by induration of the skin and particularly by epidermic thickening; picric acid is incapable of modifying these chronic lichenoid eczemas. On the other hand, the keratogenic properties of the agent find an excellent field of action in acute eczemas with swelling of the integument, superficial ulceration, and weeping. Under its influence the inflammation rapidly subsides, and the acid

forms on contact with the ulcerated and oozing surfaces a protective layer composed of coagulated proteid substances and of epithelial débris under which healing takes place rapidly. Picric acid has the further advantage that it immediately stops itching; this effect is produced in chronic as well as acute forms of the disease. In acute eczema a cure is effected in from ten to fifteen days. The method of use is as follows: A solution of twelve grammes of picric acid in one liter of tepid boiling water is painted over and somewhat beyond the affected surfaces; the parts are then wrapped in lint wrung out of the same solution, and over this is placed a covering of cotton-wool. It is important that oiled silk should not be used, otherwise maceration of the surface is pretty certain to occur. The dressing should be renewed every two or three days. Brousse recommends that before the picric acid is applied the cutaneous surface should be washed with a solution of boric acid. — *British Medical Journal*, Feb. 26, 1898.

#### MAGNESIUM SULPHATE IN TROPICAL DYSENTERY.

In a brief note to the *British Medical Journal* of February 26, 1898, THORPE extols the usefulness of this drug in dysentery. He asserts that the value of magnesium sulphate in dysentery does not appear to be generally known, judging from the scanty reference to it in the text-books, but he indorses Dr. Wyatt-Smith's experience of it from his own. In two cases under the author's care on board Her Majesty's gunboat *Peacock*, then lying in the Yang-tse-Kiang River, China, five years ago, one was treated with ipecacuanha, and eventually died in the Shanghai hospital with extensive gangrenous ulceration of the bowel; the other was given drachm doses of a saturated solution of Epsom salts, in combination with ten minims of dilute sulphuric acid, every hour, as described in *The Lancet* of October 4, 1890, and recovered without a single complication.

So striking and immediate was the effect of magnesium sulphate on the symptoms, that in any future case of dysentery the writer states he will give it first trial, before resorting to ipecacuanha with its uncertain action. Considering the number of cases which occur in the ships of the Royal Navy serving on the coasts of China and the East Indies, he thinks that this method of treating the disease should be more widely known.

Wiglesworth states that he was much interested in the memorandum communicated by Dr. Wyatt-Smith in the *British Medical Journal* of January 29 on the treatment of tropical dysentery by magnesium sulphate, as he can fully corroborate all his statements. For several years in Nicaragua, Central America, he treated dysentery with ipecacuanha, and notwithstanding its vaunted efficacy he cannot say that he knows of one single case which derived much benefit from it. The "text-books" say that a patient suffering from dysentery can retain large doses of ipecacuanha in a remarkable manner; but in his experience this is far from being correct, although anti-emetics were in all cases given previous to its administration. It was not until he read in a medical paper the treatment of dysentery by magnesium sulphate and dilute sulphuric acid that he had any success. He then gave half-ounce doses of a saturated solution of magnesium sulphate and fifteen minims of dilute sulphuric acid every two hours, with milk diet, and in the words of Dr. Wyatt-Smith it "acted like magic." In most cases pain and all traces of blood disappeared from the stools in twenty-four hours, and there was of course a complete absence of the distressing nausea which is always present in the treatment by ipecacuanha.

If the magnesium sulphate treatment were carried out, in the majority of cases tropical dysentery would be shorn of half of its terrors.

#### PNEUMONIA IN PRIVATE PRACTISE.

M. HOWARD FUSSELL writes under this title in the *Medical News* of March 5, 1898. He points out that in a disease in which, in fully one-half of all cases, treatment is apparently ineffectual, and in which recovery is frequent even when treatment is not attempted, the cases not being seen by a physician, one must speak of the value of remedial measures with great diffidence, especially as regards drugs. Much good may be accomplished by proper treatment, and it is criminal to permit a patient with pneumonia to be wholly without treatment, but the author believes that the administration of drugs or the use of local applications have absolutely no effect upon the course of this disease. In his opinion proper treatment consists of rest and care of the heart. Rest is certainly the most essential point in treatment. In a case the writer details, the

patient was doing well; there was no sign of collapse. He saw her at 10 A.M., at which time the temperature was normal and the pulse slow and steady. She arose from her bed, walked around the room, and within two hours was dead from failure of the circulation.

Another case, seen in consultation, in which resolution was progressing nicely, the temperature normal, the patient had violent post-febrile delirium. The action of her heart, which had previously been good, became rapid and irregular. A few hours' rest, obtained by means of morphine, caused the heart's action to become regular, and the patient is now well on the way to recovery.

Rest should be as absolute as possible. The patient should not be allowed to rise to have a movement of the bowels, but should use the bedpan. If delirium is present, a hypodermic injection of morphine should be given. The author states that he once acted as nurse for a noted homeopathic physician who could not be restrained in bed; he was maniacal, attempting to climb out of the window, etc. His pulse was very rapid. A hypodermic injection of one-eighth of a grain of morphine put him to sleep; his pulse fell to 100 and was for the time much improved in quality. A consultation of his homeopathic attendants resulted in detention in bed by physical force. The delirium continued, and the patient finally died.

The next most important part of treatment is care of the heart, in regard to which rest is, of course, the prophylactic measure. When, in spite of absolute rest, the heart begins to fail, strychnine, digitalis and whiskey must be used. Strychnine, given hypodermically, will frequently abort a threatened collapse and carry the heart over a critical period. It has been said that such treatment is not rational, because it is but a whip to the jaded horse. That it is a whip is true, but if the tired heart can be made to make an extra effort and pull the load over the last acclivity it may be all that is necessary to insure recovery. In all cases of impending heart failure Fussell gives strychnine hypodermically in one-twentieth grain doses every three hours. Its value was well illustrated in one of the writer's cases, a man aged forty-seven years, with double pneumonia and moderate fever, who progressed nicely until the sixth day. The heart's action then became rapid and the respirations reached the extraordinary rate of seventy per minute. This condition continued from 7 A.M. until midnight.

For some unknown reason strychnine had not been used, though oxygen, digitalis and whiskey had been employed to the fullest extent. At 8 A.M. a hypodermic injection of one-twentieth of a grain of strychnine was given, and was followed by some relief. It was repeated at 10 P.M. and also at midnight. By 2 A.M. the respirations had fallen to fifty, and from this time on convalescence was rapid. Digitalis and whiskey are valuable agents in pneumonia, but in an emergency their action is not to be compared with that of strychnine.

The author has never employed venesection in pneumonia. In one case it seemed to be demanded, but was refused. With aconite and veratrum viride he has had no experience, having always been afraid to use them.

In all of the author's first cases of pneumonia a jacket poultice was employed. It was troublesome, unclean, and uncomfortable, and except under certain conditions was soon discarded. Where there is much pain, and consequent embarrassment of breathing, the application of a poultice which envelops the whole chest affords such immediate and striking relief that its use seems justified.

When pain is severe, a small hot poultice over the affected area will give relief. Cotton jackets he still uses, knowing that they accomplish little or nothing except perhaps to quiet the minds of the patient and friends.

A cold bath when the temperature is high gives the greatest relief, and under its influence a delirious patient will frequently go quietly to sleep. In one of his cases, in which the patient died with a temperature of 107° F., he believes the fatal termination might have been prevented by the application of cold.

Local applications of ice to the affected side are theoretically correct. They certainly relieve pain, but his own experience with them has not been encouraging. He still employs them when there is a tendency to hyperpyrexia.

The pain, which is frequently the most annoying symptom, can best be relieved by the application of ice, a poultice, by means of cups, and, lastly, by the administration of opiates.

---

*THE SYMPTOMATOLOGY AND TREATMENT OF THE COMMON CLINICAL FORMS OF LITHEMIA.*

The *Medical Record* of March 26, 1898, contains an article by BARNES upon this sub-

ject. In the section dealing with treatment he expresses the belief that the treatment of lithemia is generally very satisfactory, both in avoiding the distressing paroxysms and in securing freedom from the symptoms more or less constantly present. The two cardinal rules which sum up the whole subject are: eliminate the toxic agents which cause the symptoms, and avoid nitrogenous food, from the metabolism of which the toxic agents result. It is often a matter of considerable difficulty to feed lithemics properly, because generally a complete change in diet is necessary, and the monotony of non-nitrogenous food is very unpleasant.

Milk, vegetables and cereals are the best food for lithemics, and all cases marked by pronounced symptoms should be kept strictly to the above articles. However, in the management of most cases it is necessary only to direct the patient to eat sparingly and of simple food, and to caution particularly against overindulgence in food of any kind. Stress should be laid upon the latter, because it is certain that overeating constitutes the cause of many cases of lithemia. To prescribe proteids entirely means to eliminate from the dietary most of the ordinary articles of food, and this is practically impossible. Indeed, some nitrogen in the food is necessary to replace the waste occasioned by metabolism. Meat, fish, poultry, eggs, tea and coffee should occupy an inconspicuous place in the dietary; while carbohydrates, fats and milk should make up the list from which the patient can choose. Vegetables in general and fruits are well borne; so also are cereals and small quantities of cheese. It is not necessary to eschew meat entirely; it may be allowed in small quantities at the midday meal, if special injunctions are given that moderation must be observed. The meat may be stewed, as recommended by Kolisch, by which process it is deprived of most of the extractives. If desirable, boiled fish or poultry in small quantities may be substituted for the meat. It is observed that occasionally certain vegetables and fruits disagree with the patient, in which case the offending article must be avoided. Other foods to be interdicted are salads of all kinds, fries, sweet articles—such as preserves, candies, pastries—and malt liquors. Spirits, as a general rule, are injurious, but the writer has observed that their moderate use in some cases is not disadvantageous.

Not infrequently the sudden change in the chemical composition of the diet will, as Haig

pointed out, cause an increase in the severity of the symptoms. This condition, however, is explained on physiological grounds, and, because evanescent, should be ignored. During this period of exaggeration of symptoms it is well to insist upon freedom from the cares of business and a few days' rest in bed.

The fact that the causative toxic agents are eliminated by the kidneys, bowels and skin gives the clew to the medicinal treatment of lithemia. These emunctories should all be gently stimulated by non-irritating agents. The treatment is best begun either by a brisk mercurial purge or with small doses of calomel and soda, given until free catharsis is produced. If constipation be a marked feature, this must be overcome by carefully adapted doses of cascara, given preferably in glycerin once or twice a day as the case requires.

The drugs which, in the writer's experience, produce the best results as general eliminants are the phosphate of sodium and the bitartrate of lithium. The salts of lithium have for a long time enjoyed the reputation of being of especial value in the treatment of lithemia. A series of experiments conducted by him to determine the relative values of the citrate, carbonate, and bitartrate of lithium in these cases was conclusive as to the vast superiority of the last mentioned salt. Not only is it a better diuretic, but it seems to have a specific eliminative power on the alloxuric bodies, which are probably the cause of the lithemic manifestations. Furthermore, its prolonged use is unattended by any disturbances whatever.

While it is necessary to secure satisfactory bowel movements, it is equally important to avoid drastic purgation, as this interferes with free diuresis. In most cases the phosphate of sodium has the desired laxative effect; moreover, its cholagogue action in these cases is particularly valuable. The best routine treatment for most cases of lithemia consists of the administration of the phosphate of sodium in drachm doses once a day, taken preferably in a glass of hot water before breakfast, and from five to ten grains of bitartrate of lithium taken in a glass of water three times a day. These quantities must, of course, be varied to suit individual cases. One drachm of phosphate of sodium may sometimes be repeated to advantage in the course of a day, but the quantity of the lithium salt must be determined by the amount of diuresis produced. One, one and one-half, or two of the effervescing lithia

tablets, three times daily in a glass of water, will be found to meet the requirements of nearly all cases. In accordance with Klemperer's observations, that drugs calculated to eliminate toxic agents resulting from faulty nitrogen metabolism are given to best advantage about four hours after a meal, the writer has followed the rule in the administration of the bitartrate of lithium, and has obtained the happiest results.

In nervous dyspepsia, chronic gastric catarrh, myalgia, and very often in migraine, the prognosis is favorable; but in those cases in which the clinical pictures are almost identical with these affections, but in which a lithemic condition is present, antilithic treatment is the only method attended with good results. There can be little doubt as to the accuracy of this statement; its truth the writer has many times demonstrated to the satisfaction of himself and others.

The value of the salicylates in the treatment of lithemia is, in the writer's opinion, decidedly negative. Their powers of elimination have been greatly overestimated. It is true that their ingestion is followed by increased excretion of uric acid, but this is due to an increased production of this constituent. It is well known that the salicylates increase leucocytosis; and, as Horbaczewski demonstrated, much of the uric acid excreted comes from the catabolism of the nuclein of the leucocytes. It is, therefore, manifestly improper to administer a remedy which causes increased production of any of the alloxuric bodies. Just at this point the writer expresses an opinion, based upon several years of clinical observations, concerning the therapeutic value of the salicylates in those affections for which they are commonly given. In acute rheumatism they are of decided value as analgesics; but in many cases of chronic rheumatism, and in all cases of lithemia and gout, they are of doubtful therapeutic effect.

The excretory activity of the skin is best maintained by frequent bathing. Hot-water baths, taken either every day or on alternate days, are of positive value in the treatment of lithemia. The reputation of the many lithia waters is probably due more to the water they contain than to any of the salts; at any rate they are not to be relied upon, exclusive of other medication. Good pure water, taken frequently during the day in liberal quantities, is to be commended.

The general treatment above detailed—viz., the use of a non-nitrogenous diet and

frequent bathing, the administration of phosphate of sodium and bitartrate of lithium, given preferably in the form of effervescent lithia tablets—will generally suffice to rid lithemics of not only the distressing bilious and migrainous paroxysms, but also of the symptoms referable to the gastro-intestinal tract.

The two classes of headaches mentioned above have yielded to this treatment when cannabis indica, the iodides, salicylates, methyl blue, and the host of other remedies ordinarily used for obstinate headaches, have failed. It is often necessary to treat individual symptoms when pronounced enough to occasion distress. In those cases in which the symptoms of acid dyspepsia are more or less constantly present, which symptoms occasionally culminate in an attack of biliousness or "sick-headache," the remedy popularized by Dr. J. P. Crozer Griffith has given excellent results. It is an alkaline aromatic, the formula of which is:

- R. Ol. caryophylli, f 3 j;  
Sodii bicarb., f 3 ij;  
Chloroformi, gtt. cxx;  
Tr. cardamomi comp., q. s. ad f 3 iij.
- M. S.: Teaspoonful to be taken after each meal.

The writer has found the efficacy of the above mixture increased by the addition of the oil of cajuput in doses of from five to ten minims. In this class of cases, particularly those in which there are present much flatulence and other symptoms of intestinal indigestion, associated with headaches, a compound tablet of beta-naphthol 3 grains, eucalyptol  $\frac{1}{2}$  grain, guaiacol  $\frac{1}{2}$  grain, thymol  $\frac{1}{2}$  grain, given three times daily, is of value. The best results are obtained in the general treatment of lithemia by adopting a brisk eliminative measure during the first two weeks, then reducing the quantities of the drugs for the second fortnight, then again reducing to a minimum, or intermitting them entirely for the fifth and sixth weeks. In many cases small doses of phosphate of sodium and bitartrate of lithium, given continuously, will keep the symptoms in abeyance.

#### *THE TREATMENT OF CRUSTA LACTEA, OR INFANTILE ECZEMA.*

Dr. KISTLER of Allentown, Pennsylvania, in the *Medical Record* of February 12, 1898, writes on this topic. After stating that the occurrence of this affection in infants and children under four years of age is common, its clinical appearance marked, and the op-

portunity for its complete observation by every practitioner of medicine frequent, he goes on to describe his method of treatment.

Milk tetter occurs among the rich as well as among the poor, and is a most annoying affection, not only to the little sufferer, but to the mother or nurse who has charge of the case, when sleep is so frequently disturbed by the child's distress. In the etiology of infantile eczema, an inherited or congenital tendency to eczematous inflammation may exist, and such cases as a rule are more difficult to cure than cases in which the active cause can be demonstrated.

There are three chief indications to be fulfilled in attempting to cure this distressing complaint, namely, elimination, palliation of local distress, and correction of malassimilation and restoration of strength—which latter are, indeed, the main factors.

For elimination, calomel in purgative doses—one to two grains (preferably tablet triturates), according to age—the object being to stimulate the liver and to obtain a perfect clearance of the stomach and bowels; the dose to be repeated according to circumstances—once, twice or thrice a week, as the patient's condition may indicate.

For alleviation of local distress, itching, etc., the benzoated oxide of zinc ointment is an old but capital application to soothe and protect the skin. The following is another excellent dressing :

- ℞ Salicylic acid, 2 parts;
- Bismuth subnitrate, 40 parts;
- Corn-starch, 15 parts;
- Ointment of rose water, 100 parts.

These ointments should be spread thickly on pieces of muslin and carefully applied, especially in the moist variety. When there is merely a dry squamous form of the affection present, and in the face, the ointment can be rubbed over the surface of the skin. These salves may be repeatedly applied until a thick, white and rather dry coating forms upon the surface of the skin, which greatly lessens the itching and the redness, and allows a healthy epidermis to form. Soap and water are powerful agents to aggravate this existing inflammatory condition, and the frequent washing of an infant or child affected with eczema is to be strenuously interdicted.

The third indication, restoration of strength, is accomplished by correcting the malassimilation and restoring the blood to its normal condition. The best agent for effecting this is that valuable alterative tonic, arsenic;

Fowler's solution, in doses of one to three drops, according to age, may be given. It should invariably be conjoined with iron; the ammoniated citrate, so readily soluble in cold water, combined in proper doses, is a very convenient and efficient preparation for this purpose. The same should be administered three times a day. The elixir of gentian and tincture of chloride of iron in suitable doses are also an eligible tonic and stomachic in this class of patients.

Hygienic and dietetic measures must likewise not be neglected.

#### PRIMARY TREATMENT OF POST-PARTUM HEMORRHAGE.

M. W. CURRAN, of New York, writes a valuable paper on this subject in the *Medical Record* of February 12, 1898. He points out that it is our obvious duty in these cases to compare them with the parallel obvious duty in ordinary surgery. A man's leg is rapidly cut off by a circular saw. From a multitude of small mouths spurts the arterial blood. In a few moments, unless prevented, the amount of available blood in the body will sink below that necessary to keep going the most important nerve centers. What is to be done? Should the surgeon douche the wound with hot or ice-cold water, or pour styptics over its spouting surface, or set to work and methodically tie all these vessels from the raw surface? He would laugh at the question, because here the procedure has been settled once for all on scientific grounds, and he knows for certain the one thing he must do first. The success of all depends on this primary duty, which is to compress the main vessels at once, and not until all the oozing or spouting was secured in detail would he relax this pressure. Let us consider the condition of the patient at this time. The abdominal wall has been stretched to its utmost for many months over the enlarging uterus. Now the uterus is emptied of all resisting contents, and the walls fall limp and flaccid over the abdominal cavity. The muscles, which normally might prevent by their firm contraction, are now powerless, and many weeks must elapse before they are again capable of resisting the pressure of a hand placed upon them. In this condition it is the easiest thing in the world for the obstetrician's hand to find and compress any structure in the abdomen. The aorta is placed in front of the one resisting firm material left, the lumbar spine.

Between the obstetrician's hand in front and the vertebræ behind the aorta can be absolutely shut; no more blood can pass, and no more blood will be lost. What remains in the bleeding vessels below the occluding hand when the driving power of the heart is shut off tends to clot, especially at their open extremities; what blood remains in the circulation above is kept for the use of the all-important nerve centers, and as more and more blood comes in from the veins, especially of the lower extremities, for the vena cava is carefully avoided, this reserve increases and respiration and circulation in the most important parts are increasingly provided for, while all the time the tissues which require rest, the ultimate ligatures, the uterine muscular fibers, are obtaining and profiting by that rest and becoming more and more fit to do the work of which they are perfectly capable when once they have recovered their condition. When necessary time has elapsed and their contractility has returned, then and then only is the time for their stimulation. What would be thought of the surgeon who held the femoral artery for a minute and then let it go before the vessels were closed on the wound front, and what is to be thought of the advice given by some leading authorities?

Barnes says: "I have occasionally derived advantage from it, and look upon it as a momentary resource."

Playfair thinks that "as a temporary expedient it should be borne in mind and adopted when necessary."

Jewett considers it "very effectual as a temporary expedient."

Lusk thinks that "compression of the aorta through the abdominal wall is capable of rendering temporary service."

"Should all these measures fail, try to compress the abdominal aorta."

It is precisely this half-hearted advice, which has a dozen resources in stock and trusts none of them, which is to blame for the general muddle-headedness of mind which is bound to result from a consultation of authorities. If one thing does not succeed, try something else; but the patient should no longer be considered doomed, for whom the physician is bound to do everything, in order to cover his reputation at the inevitable inquest.

Macewen has "effectually controlled the abdominal aorta by throwing the weight of the body on the aorta through the closed right hand, placed a little to the left of the

middle line, the knuckles of the index-finger just touching the upper border of the umbilicus. With the left hand the arrest of the blood current is ascertained by feeling the femoral at the brim of the pelvis. Only enough weight to arrest the femoral pulse is required. If the patient vomits or coughs, the pressure must be increased, lest the hand be lifted from the aorta by the abdominal muscles."

In order to compress the abdominal aorta, it is not necessary but rather injurious to move the patient from the ordinary dorsal position. With the patient lying, as she usually does, flat on the back, the obstetrician's hand is easily applied under her without even disturbing the coverings of the bed, and avoiding exposure, which is the *sine qua non* of all remedial measures. The ulnar surface of the closed left hand—the physician standing on the right-hand side of the patient—should be laid gently but firmly across the aorta, which should then be compressed against the spine, while the right hand should feel for and compress the uterus. The hands may be changed from time to time, but the compressing hand should never be lifted until the other is in position above or below it and has taken up control of the vessel. The time during which compression is needed will vary with every case, and must depend wholly upon the cessation of hemorrhage and on no other factor. It is convenient and always necessary to have an assistant at hand, who may relieve the tired muscles of the original attendant. Two points are of great importance: First, inasmuch as the solar, epigastric and mesenteric plexuses lie over and around the aorta, pressure must be shifted upward or downward from time to time. The pressure on the aorta does not matter, but too long continued pressure upon any one point of the sympathetic does. Secondly, when pressure is taken off ultimately it must be very gradually done. The uterus should be felt to be firmly contracted; the aortic pulse should be firm, strong, and fairly slow; and the effect of releasing the current should be most carefully watched. If there is the least return of flow, the uterine ligatures are not yet to be trusted and compression must be resumed. This, then, is the primary duty. Once done and persisted in from the earliest possible moment until the desired firm contraction has been obtained and can be manifestly relied upon, the patient is safe as far as any earthly means can make her; and, with the entire self-possession which perfect

security gives, the physician can quietly and without needless hurry put into force the secondary measures which are to bring about the secondary result—namely, the firm and lasting uterine contraction. All these secondary measures require an appreciable amount of time for their satisfactory action; moreover, they all act best on muscular fiber which is recovering or has recovered its contractility. In this alone is seen the fatal mistake of considering them of primary importance, and of wildly flying from one to the other, vainly seeking for a result which the inherent conditions present render impossible or at best extremely improbable. These secondary measures are: hypodermic injections of ergotin, brandy by mouth or rectum, raising the foot of the bed, hot bottles around the trunk, wrapping the head in hot flannel, kneading gently the uterus with the disengaged hand, removal of any clots or placental debris—which now that the main source of blood-supply is shut off can be done with far more safety, because with calmness and deliberation—and examination of the os, cervix and perineum for tears, and their repair.

But it may be said that this advice is only theoretical, and that no cases are on record to prove it. The writer states that he suspects that the method is more in use among practical men than one would suppose from a perusal of the literature on the subject. Practising autotransfusion as described for cerebral anemia, when aortic pressure is an easier and better method, or using Monsell's solution as a styptic, with its danger of producing gangrenous endometritis and secondary infection, in preference to applying the hand to the aorta, may be in favor with the savants of the profession, but hardly with another human being endowed with a healthy perception of the fitness of things, and who by experience realizes that in every case, whether complicated by retained placental fragment, torn cervix, or any other condition, the one and only measure of primary importance in the treatment of post-partum hemorrhage is compression of the aorta.

---

*GLAUCOMA AND THE INFLUENCE OF  
MYDRIATICS AND MYOTICS UPON  
THE GLAUCOMATOUS EYE.*

Dr. EDWARD JACKSON contributes to the *American Journal of the Medical Sciences* for April, 1898, an article with this title. With reference to the use of mydriatics, he thinks we are justified in saying that in general they

should not be applied to eyes that are glaucomatous or upon the verge of glaucoma. In such eyes the dilatation of the pupil they commonly produce is dangerous, and may cause increase of intra-ocular tension, which, if not speedily relieved, will do permanent damage. But the risk of this effect from a mydriatic is not to be guarded against by fixing an age limit before which mydriatics may be considered safe and after which they should not commonly be employed. In the great majority of eyes a mydriatic cannot cause glaucoma at any time of life, while, on the other hand, a few patients are affected with the disease even from childhood. The danger is best guarded against by bearing in mind the symptoms of glaucoma, and always looking for them before ordering a mydriatic, especially by a careful ophthalmoscopic examination.

In very rare cases careful examination may not reveal the imminence of glaucoma, yet when the mydriatic has been used the outbreak may occur. In such a case the usual remedies for glaucoma should be promptly resorted to. The mydriatic should be stopped and iridectomy strongly urged. With the proper iridectomy promptly done the prognosis for complete permanent cure is excellent, the results being decidedly better than in cases discovered at a later stage when the glaucomatous outbreak has occurred spontaneously. Indeed, if the patient permits the proper, immediate treatment of his case, the fact that an outbreak of glaucoma has been evoked by the use of a mydriatic is probably a cause for congratulation rather than for regret. For the eye was, in all probability, doomed to the disease, and the earlier application of the remedy gives the better chance for complete and permanent cure.

The author believes it would be perfectly proper, after explaining the matter to the patient, and getting his assent to prompt iridectomy if it should be indicated, to use homatropine as a test for the presence of glaucoma at the earliest stage in doubtful cases.

If the patient refuses iridectomy, eserine should be promptly resorted to in such strength and with such frequency as may be necessary for the reduction of the pupil. In the case of a glaucomatous outbreak following the use of a mydriatic more persistent in its action than homatropine, it would be proper to shorten the period of mydriasis by tapping the cornea and evacuating the aque-

ous humor, preparatory to the efficient use of eserine.

In any case of glaucoma in which the pupil is firmly bound down by adhesions, or is otherwise so fixed that mydriasis cannot cause thickening of the iris opposite Fontana's space at the angle of the anterior chamber, especially if the application of eserine aggravates the symptoms, it is justifiable to apply atropine or some other mydriatic, and in a small proportion of cases such applications will be of marked benefit.

Myotics are beneficial in glaucoma only when the pupil is still movable—that is, chiefly in the earlier stages. When not beneficial, they are usually distinctly injurious.

If for any reason iridectomy cannot be done, myotics are always to be tried in the earlier stages of the disease. If they cause marked improvement they may be continued so long as the improvement persists. If they reduce the eye tension they may be continued so long as they keep the tension down; if they promptly relieve attacks they may be continued so long as attacks are rendered less severe and frequent, and leave no permanent impairment of function, either of central vision or of the field, in the interval. But in the vast majority of cases there will come a time when the influence of the myotic, although still favorable, is less favorable than it has been; and after this it is liable to rapidly lose its power to do any good at all. Hence, whenever this period arrives the patient should be warned that the myotic is insufficient, practically worthless, and an operation, preferably iridectomy, gives the only chance for escaping complete blindness and, perhaps, intense suffering.

#### *PILOCARPINE IN CHORIO-RETINITIS AND VITREOUS OPACITIES.*

The *Ophthalmic Record* for February, 1898, contains an editorial by de Schweinitz on this theme. Soon after the introduction of the alkaloid of the *Pilocarpus jaborandi* into the general medical armamentarium, the attention of ophthalmologists was directed to its value in ocular therapeutics, quite independently of any local action which it exercised upon the accommodative apparatus or the intra-ocular tension. Its extraordinary influence as a diaphoretic, as a remedy which facilitated the removal of effusions, and as a medicament which seemed, under certain circumstances, to powerfully stimulate and alter the nutrition of diseased areas, and even of

tissues that were not diseased—for example, the hair bulbs—led to its use for the relief of exudative inflammatory affections, especially when located in the uveal tract. Some of the results following the use of this remedy in the treatment of irido-choroiditis with vitreous opacities, equatorial choroiditis with circumscribed choroidal atrophy, diffuse infiltration of the retina and hyalitis, and even the neuro-retinitis of Bright's disease, as recorded by Landesberg in 1881 and von Schroeder in 1883, were strikingly favorable, and as its efficiency became established it was soon recognized as an important remedy in the management of cases of this character.

Although clinical experience has not indicated its utility in the management of keratitis, for example, of the interstitial variety, it has proved its great use in certain types of iritis and irido-cyclitis—as, for example, those recorded by Buller some years ago—its value, in the writer's experience, being particularly great in the iritis and kerato-iritis which sometimes seem to be of gonorrheal origin, and even in those varieties which are probably gouty in nature.

Not only, however, does the remedy seem to be active when it is used in large and diaphoretic doses, but also when employed in more moderate amounts. Thus, in 1892, in the *Archives of Ophthalmology*, Dr. James A. Spaulding contributed an excellent practical paper on idiopathic vitreous hemorrhages, concluding that the most efficient treatment of this affection required the hypodermic use of small doses of pilocarpine, believing, moreover, that it was not necessary to produce visible physiological effects for the remedy to be useful in the eye. Shortly afterwards, in the *THERAPEUTIC GAZETTE*, the writer described a treatment of vitreous opacities with the fluid extract of jaborandi, and reported a number of cases in which the vitreous had cleared under the influence of the drug when the opacities were hemorrhagic in origin, and also when they had been associated with types of quiet iritis and low-grade choroiditis. None of these cases, of course, were of syphilitic origin.

Recently Dr. Howard F. Hansell (*Philadelphia Polyclinic*, Nov. 20, 1897) has published a most suggestive and instructive paper on the use of pilocarpine in non-syphilitic central retino-choroiditis. In one case the vision was raised from 20-200 to 20-20(?) in a month, and in another case from 20-50 to 20-20 in one week; in two other cases there was marked visual improvement.

Dr. Hansell's description of the action of pilocarpine under these circumstances is so clear that it is quoted in his own words, namely: "The efficiency of pilocarpine is to be attributed to the inordinate activity of the lymph system induced by its presence. By depriving the peripheral vessels of a large portion of their fluid contents those of the internal organs meet the deficiency, thus eliminating morbid products, together with physiologic excretions." An interesting fact in connection with Dr. Hansell's cases is that potassium iodide and mercury had been previously exhibited in large doses without avail.

A word as to the manner of administration. Pilocarpine is to be preferred and the hypodermic method should be adopted. If in rare instances this is not advisable, or is strenuously objected to by the patient, equally good results, although perhaps not so promptly or actively produced, may be secured by enemas of the fluid extract of jaborandi. The hypodermic dose of pilocarpine may vary from a twelfth to a sixth of a grain, under ordinary circumstances, and should be repeated every second, third or fourth day, according to the patient's power of resisting so active a remedy. Now and then, probably owing to idiosyncrasy, very disagreeable results follow its use, as no doubt has been the experience of every surgeon who has employed it. Thus, there may be marked nausea, evidences of pulmonary edema, and occasionally serious cardiac depression. It has been the writer's habit to administer about an hour before the injection thirty drops of chlorodyne. The use of this remedy in this manner has been advocated by so high an authority as the professor of therapeutics in the University of Pennsylvania, and will usually prevent the nausea. During the days devoted to the pilocarpine treatment, small doses of tincture of digitalis may with advantage be administered, tending as they do to prevent cardiac depression and to steady the circulation. Occasionally a patient will be found who curiously resists the action of pilocarpine, while in others the remedy, instead of exciting diaphoresis, will exceptionally produce the untoward symptoms already noted.

#### TREATMENT OF HEMOPTYSIS.

The *Clinical Journal* of January 5, 1898, contains an article by Biss on the treatment of hemoptysis. He believes that in the treat-

ment of pulmonary hemorrhage some stress must be laid in the first place upon the moral management of the patient. The alarm he naturally feels should be relieved by the assurance—if it can be truthfully made, as in most cases it can—that the hemoptysis is not likely to prove fatal. He should be enjoined to be restful and quiet, and care should be taken to avoid the injudicious fussing of relatives and others around the bed.

Should the patient be found lying upon a bed or couch, it ought to be carefully considered whether it be wiser to move him or to leave him undisturbed; but the writer thinks in any case the effort should be made to loosen, and if possible to remove, all tight clothing, not by taking the clothes off, which would be extremely injudicious, but by loosening or cutting them open as far as may be possible without unduly disturbing the patient. The examination of the chest by percussion and auscultation should be avoided, except so far as listening to the breathing over the front of the chest, for the site of the hemorrhage may frequently be determined in this way. The sensations of the patient are not a safe guide, and must be regarded with caution. The importance of ascertaining the source of the hemorrhage, where this is possible, is great, for over that spot we should apply the ice-bag if we decide to use it; and in some cases when a patient has bled profusely into one lung, and is half suffocated in consequence, an appropriate change of position may enable him to cough up the blood which has collected, and avert impending asphyxiation.

Opinions are divided as to the advisability of applying ice to the chest; some think that it does no good, others think that it tends to induce catarrh. The writer is of the number who believe that in many cases this is a valuable method of treatment, and ought unhesitatingly to be adopted. He has not seen it produce catarrh, and he has many times seen it do at least apparent good. Moreover—and this is a point of some importance—the feeling that a means of treatment which appeals strongly to his senses is being employed for the arrest of the hemorrhage has a soothing effect upon the patient's mind. The same remark applies to dry cupping, but this is not altogether unobjectionable on account of the physical disturbance which it is apt to produce, and he does not recommend it.

Whether the cough ought or ought not to be relieved in any given case of hemoptysis is a question which must be decided at the bed-

side. Unless the cough is severe it does not need treatment; on the other hand, if it is necessary for the purpose of clearing the lungs of blood, it is a great question whether good would be done by checking it. There is, however, an intermediate class of cases in which it is most desirable to reduce the frequency and severity of the cough, and in these cases he thinks a hypodermic injection of morphine is to be preferred to any other means.

Patients spitting blood, especially soon after they have begun to spit blood, and if in large quantity, are frequently restless and alarmed; sometimes, on the contrary, they are passive and half collapsed. In cases of nervous excitement he thinks the employment of opium in some form is most desirable, for in no other way can we so effectively secure that quiescence of body and mind which is necessary to the well-being of the patient.

In hemoptysis it is generally, not to say invariably, advisable that the bowels should be opened as soon as possible, and be kept freely opened; for as the abdominal circulation is capable of containing a large part of the total amount of blood, it is not unreasonable to believe that the induction of brisk bowel action by means of purgatives will cause a large amount of blood to pass into the intestinal vessels, and that this may tend to reduce the tension of the circulation elsewhere. He lays stress upon this point, not only on account of its intrinsic importance, but because he has frequently found in cases of hemoptysis that patients have been treated without any regard to these considerations, the bowels having been kept confined by the administration of astringents and opium, sometimes without design, and sometimes from a belief that the patient is in a more favorable position if spared the exertion of defecation. This need not be feared, however, if the patient is properly nursed. It is unnecessary to say that he should not leave the recumbent posture, and that the use of the bedpan should be enjoined. He does not recommend the administration of enemata if they can be avoided, for many persons become excited under their use, and the restlessness induced by the application of a remedy to which an objection is felt might induce further bleeding. Probably nothing is better than the immediate administration of five grains of calomel, followed by a saline purgative at an appropriate interval; after which free action of the bowels may be maintained by adding to the mixture to be given

some sulphate of magnesia along with a carminative, such as syrup of ginger, in sufficient quantity to produce two or three watery stools daily.

Our knowledge as to the exact pharmacological action of most of those remedies which are in repute as remote astringents is very imperfect, and even in some cases contradictory; and for this reason it is doubtful whether there is any advantage in the administration of certain drugs which in days gone by have been held in regard as internal styptics. Among these may be named gallic acid and ergot, the former of which is objectionable on account of its tendency to constipate the bowels; and as to the latter, there is some reason to believe from recent researches that while it contracts the smaller systemic arteries it has no effect upon those of the lungs, and that it may indirectly tend rather to raise the tension of the pulmonary circulation. There is very little evidence to show that hamamelis, dilute sulphuric acid, and other astringents of this class, have any definite effect upon the small vessels of the lung. More, perhaps, may be said for turpentine, the action of which in the hemorrhage of purpura and scurvy is recognized to be of great value. In many cases the writer leans to its employment conjoined with sulphate of magnesia, and sometimes opium also.

---

*REPORT OF TWENTY-NINE CONSECUTIVE INTUBATIONS FOR DIPHTHERITIC CROUP, WITH TWENTY-SEVEN RECOVERIES, ALL TREATED WITH ANTITOXIN.*

WAXHAM, of Denver, has made a report of twenty-nine cases of intubation with the combined use of antitoxin in the *Archives of Pediatrics* for March, 1898. All the cases were seen in consultation, and in all of them the operation was urgently required. Three were under two years of age, with two recoveries, or 66⅔ per cent.; eight were two years old, with eight recoveries, or 100 per cent.; six were three years old, with six recoveries, or 100 per cent.; six were four years old, with five recoveries, or 83⅓ per cent.; two were five years old, with two recoveries, or 100 per cent.; and four were six years old, with four recoveries, or 100 per cent. Total, twenty-nine cases with twenty-seven recoveries, or 93.1 per cent., a mortality of only 6.9 per cent. This great reduction in the mortality is to be attributed to the full and free use of antitoxin in all the cases.

### THE TREATMENT OF MIGRAINE.

At a recent clinical lecture given at the Hospital Laennec by HIRTZ, this subject was considered. After a historical *résumé* of the various forms of treatment which have been recommended for this painful condition, he mentions the fact that Pare practised excision of the temporal artery, Avicenne employed opium and absinthe, Tissot commended the use of venesection and emetics, and the tincture of cocchinella and *Paullinia Sorbilla* have acquired celebrity in its treatment. Sydney Ringer has employed an infusion of half to a drachm of chamomile to combat the attack. Antipyrin is of advantage in some cases, the dose varying with the individual. As much as forty-five grains may be needed for the cure after an attack has once thoroughly begun. The relief obtained from the antipyrin may be increased by giving with it eight or ten grains of bicarbonate of sodium. If the stomach is non-retentive antipyrin may be given in the dose of thirty to forty-five grains by the rectum, with twenty to thirty drops of laudanum. Often caffeine given by the mouth or hypodermic injection is useful. The following preparation is used:

- ℞ Caffeine,  
Benzoate of sodium, of each 4 drachms;  
Peppermint water, 4 ounces.

A coffeespoonful of this solution may be given every two hours.

For hypodermic use the following may be employed:

- ℞ Caffeine, 40 grains;  
Benzoate of sodium, 45 grains;  
Distilled water, 150 grains.

Thirty minims of this may be given hypodermically.

Acetanilid and phenacetine may be given in other instances, usually in the dose of four or five grains four or five times a day. On the principle that the attack may be due to spasm or paralysis of the blood-vessels, nitrite of amyl may be employed in those cases with high tension, and ergot in cases of low tension. Brunton's recommendation that full doses of sodium salicylate should be given combined with bromide of potassium is mentioned, and Schumann's statement that methylene blue is of service in spasm of the blood-vessels is mentioned. It may be given in capsules in the dose of two grains three or four times a day. Full doses of cannabis indica are also suggested, and it should not be forgotten that sometimes eye strain is re-

sponsible for the condition. As a prophylactic the following may be employed:

- ℞ Sulphate of quinine, 45 grains;  
Powdered digitalis, 20 grains;  
Syrup, a sufficient quantity to make 30 pills.  
One every night continued for several months.

If the patient is rheumatic or gouty careful attention should be paid to his diet. Alkaline mineral waters, such as are obtained at Carlsbad, Tarasp or Vichy, are used. Such cases may also receive the following pill:

- ℞ Valerianate of quinine, 15 grains;  
Extract of colchicum, 4 grains;  
Extract of digitalis, 4 grains;  
Extract of aconite, 2 grains.  
Make into ten pills and give one at night after dinner.

When migraine is due to neurasthenia it is much benefited by living in the country, by moderate muscular exercise, and avoidance of professional occupations. Arsenic is also a remedy not to be forgotten, and hydrotherapy, static electricity and psychotherapy are valuable adjuncts to treatment.—*Journal des Praticiens*, Dec. 11, 1897.

### THE TREATMENT OF ACUTE EDEMA OF THE LUNGS DUE TO AORTIC LESION.

*La Presse Médicale* of March 5, 1898, advocates the following treatment in this condition:

In the presence of severe valvular lesions it is necessary that the patient shall lead a regular life, shall not be fatigued, shall be at least nine hours in bed, and shall rest for two hours after each of her principal meals. The diet should consist of broths, well cooked tender meat, fish, light wines and sparkling waters, and moderate amounts of coffee and tea. Small quantities of liquid should be taken with each meal so as not to overload the stomach. In the way of medication it will be well every week or two to alternate with small doses of iodide of potassium and theobromine. A rectal injection should be taken daily amounting to about a pint of warm water to keep the bowels active, and it is well to have the body energetically rubbed with flannel dipped in alcohol for ten minutes every day. Should the physician be called to see a case during an acute stage of illness when these prophylactic measures cannot be instituted, or should the patient subject herself to unusual fatigue or excessive eating, she may be suffering from a sensation of palpitation, retro-sternal pain,

cardiac anguish, general wretchedness, impaired respiration, and cough. The cough may be dry or it may bring up small quantities of whitish mucus; more rarely it is pink or even red in hue. The expectoration usually becomes more abundant after an attack has lasted some time. If the difficulty in respiration is very severe the patient may break out into a cold sweat and may have cyanosis, turgid jugulars, and great anxiety for air and a feeling of impending death, the pulse being small and rapid; the extremities may feel cold, and râles will be found distributed throughout the chest, particularly at the two bases. There may be some dilatation of the right heart. The movement of the thorax is tumultuous owing to the irregularity of the heart's action.

The diagnosis in the presence of such symptoms will probably be acute asphyxia, edema of the lung with functional trouble of the cardio-pulmonary plexus. The indications to be met will be to overcome the congestion of the lung, to correct disorder of the vascular system, to improve the tone and regularity of the cardiac systoles, and to reassure and comfort the patient. In some instances immediate resort to venesection should be had, and it may be necessary to give some powerful cardiac and nerve stimulant.

The definite treatment consists in the application of mustard plasters over the sternum, bleeding from the median basilic vein to the extent of five or six ounces, the inhalation of a few drops of sulphuric ether poured upon a handkerchief, hot applications to the trunk and to the lower extremities, and it may be a hot foot-bath. Assure the patient, with an air of calmness and authority, that she will recover. It may also be advisable to inject hypodermically into the abdominal wall thirty to sixty minims of the following solution:

- ℞ Caffeine, 40 grains;
- Benzoate of sodium, 45 grains;
- Distilled water, 2½ drachms.

In the way of nourishment small draughts of hot or cold milk may be given. Absolute rest in bed is to be insisted upon in some cases; if the bowels are at all confined a mercurial purge will be of advantage. After the acute attack passes off the diet should consist of milk in small quantities given either hot or cold every two hours. An egg may also be given each day. Care should be taken during recovery that exercise is not resorted to too early.

#### CONCERNING CATARACT EXTRACTION— A REVIEW WITH COMMENTS.

Dr. G. E. DE SCHWEINITZ, the well known ophthalmologist of Philadelphia, contributes an interesting article embodying his views on this subject to the *Ophthalmic Record* for February, 1898. In his belief, in corneal section the disposition to make the incision exactly through the corneo-scleral junction, or through the transparent margin of the cornea, continues to be general, the height of the flap, or in other words, the extent of the corneal periphery which is included, varying according to the method of extraction which is adopted. It is generally conceded that for the proper expulsion of the lens in combined extraction, a flap embracing about one-fourth of the corneal periphery is sufficient. When the cataract is large, it is safer to include fully one-third of the corneal periphery. For the extraction of full-sized cataracts by the uncombined or simple method, the section may comprise nearly or even wholly the upper half of the cornea. Variations from these dimensions, however, are common, according to the experience and judgment of individual operators. Indeed, there can be no arbitrary rule—the probable size of the lens and the character of the cataract are the governing factors.

If, as Knapp has long advised, the knife remains in the same plane throughout, and the blade is turned neither forward nor backward at the completion of the section, a small conjunctival flap results, which is rather an advantage than otherwise. In Professor Snellen's operation the incision occupies half the circumference of the cornea, and lies in the apparent corneo-scleral margin. A large, broad, conjunctival flap is made after the section of the corneo-scleral margin is completed. This conjunctival flap possesses several advantages: it conserves the vitality of the cornea, promotes healing, and prevents iris-prolapse. The procedure has been commended by Berry, Landolt and other operators, but, owing to the hemorrhage which sometimes follows the formation of conjunctival flaps, they have been condemned by so experienced an operator as J. A. White, of Richmond.

It will be remembered that the late Dr. Williams, of Boston, was accustomed to make a Lebrun incision, and to place a small suture in the apex of the flap. His son, Dr. C. H. Williams, after simple extraction, when a small conjunctival flap remains, places in the flap one to three sutures. A strong advocate

of suture after extraction is Kalt, in France. The reviewer is impressed with the value of a conjunctival flap, and although he has not used sutures to close the wound after extraction, he has placed them with advantage after excision of a prolapsed iris.

Differences of opinion in regard to the best method of performing capsulotomy continue. It would seem that peripheral capsulotomy, as practised by Knapp, possesses the greatest advantages, if it is understood that needling of the capsule later on is a necessary procedure—is, in other words, as Knapp has stated, the final stage of cataract extraction. An opening by means of a central crucial incision possesses disadvantages, but these are not present if the incisions are made in the form of a T. Excision of the center of the capsule with forceps is usually reserved for those cases in which there is manifest thickening of this membrane. Nevertheless, as is well known, the routine practise of capsulotomy with forceps is advocated by many experienced operators.

The disposition to perform "simple extraction" continues to be very general, or perhaps the procedure has found more universal favor, although now and then an operator of experience has decided to return to the "combined method." There seems, however, to be a greater tendency to select cases, or rather to separate those suited to the operation with iridectomy from those suited to the operation without excision of a piece of the iris. To be sure, the old fear of prolapse of the iris, which for a time was the chief objection to simple extraction, is passing away. Indeed, Berry has gone so far as to state that iris-prolapse, if the operation is performed after the manner of Snellen, need not be considered. He is, as are most surgeons, however, careful to make an iridectomy if the iris does not at once undergo easy, spontaneous replacement, or if it is not readily replaceable by the ordinary methods.

It is interesting to note the character of cases selected for the combined method of extraction. Thus, Berry excludes from simple extraction cases of hard, nuclear, black cataract in old people, and of overripe cataract with capsular opacities and disease of the suspensory ligament; also cases in which there is a very shallow anterior chamber, and in which there is a foreign body in the lens, or in which there are iritic adhesions. So, too, he prefers combined extraction in nervous and unruly patients. In addition to the

cases catalogued by Dr. Berry, the reviewer considers those in which the ball is hard, the lens large, and the iris not readily dilatable, or where there is ciliary irritation and the cataract is not yet ripe, more suited to the combined than to the simple method.

Now and then reports of an attempted revival of the extraction of cataract in the capsule appear. For example, Gradenigo after section ruptures the zonula through its entire length with a small hook and then delivers the opaque lens.

With reference to the treatment of prolapse of the iris as a complication of simple extraction of cataract, a good many surgeons follow Knapp's advice to cut off the prolapse and reduce the edges of the iris if it is discovered within a few hours after its occurrence; if it is not seen early, to allow it to remain until the eye is quiet, when, if there is staphylomatous bulging, the protrusion may be abscised, or, in other words, treated as a staphyloma of the cornea.

The conservative treatment of iris-prolapse, however, even when discovered early, is gaining ground, as may be inferred from the recent communications on this subject by Dr. Robert L. Randolph, Dr. Joseph A. White, and others. Under suitable bandaging the prolapse flattens out and operative interference seems rarely indicated. In the discussion just referred to, the doubtful value of eserine in restoring a prolapsed iris was emphasized, because, as Dr. Randolph points out, it is apt to heighten the condition of irritation and does not seem to have much power in pulling the iris into place. Atropine, on the other hand, does not increase the hernia and lessens irritation. It is taken for granted that a compress bandage is applied during the treatment.

While the belief of Dr. John E. Weeks, expressed two years ago, that "it will not be long before the artificial methods of ripening cataracts will be entirely abandoned," may not yet have been realized, it is safe to state that the practise of ripening cataracts, whether by discission, Förster's method, or the Boerne Bettman, or the White-Pooley operation, appears not to have gained favor with the profession. If patients will not wait for Nature's method of ripening, it seems preferable to extract the unripe lens, and if necessary to deal with remnants by secondary discission. Indeed, Elschnig believes that all senile cataracts in patients over fifty are readily removable, whatever the condition of nucleus and cortex, and he is ready to extract as soon as

vision becomes too poor to permit the patient to follow his ordinary vocation.

It is desirable that more information should be available with reference to the duration of treatment and the visual acuity after the extraction of unripe cataract. Statistics thus far published are quite as favorable as those relating to ripe cataract. This information is particularly needed on account of the frequent advertisements in the public prints of methods of absorbing cataracts employed by irregular practitioners. Patients, naturally depressed by a period of semi-blindness, are apt to be deluded by these advertisements into undergoing treatment, which, to put it mildly, is at least valueless.

From the very fact that preliminary iridectomy is usually recommended in cases where serious complications are apprehended, or where for any reason an extraction in one eye has terminated unfavorably, we may assume that there is a well-founded faith that this procedure improves the patient's chance of recovery. It would not be possible to discuss the advantages and disadvantages of preliminary iridectomy in this brief review, nor indeed is it necessary, as the whole subject has been very elaborately considered in the April number of the *Annals of Ophthalmology*, by Dr. W. Franklin Coleman, who places himself on record very decidedly as believing that this is the safest method of extracting cataract, and one which should be commended to operators of limited experience.

Except in rare instances, in which the cataract is removed in the capsule, or in which a large piece of the anterior capsule has been removed with capsule forceps, sooner or later the division of the membrane is required if the highest type of visual success is to be obtained. Various modifications of the knife-needle continue to be used by most surgeons, although a few, like Schweigger, have abandoned needles, or knife-needles of any description, and divide all so-called secondary cataracts with scissors introduced through a small wound made with a broad needle. Da Gama Pinto's very large experience with operations for the relief of secondary cataract indicates the value of a narrow Graefe cataract knife as an instrument for dividing the membrane. This surgeon, in addition to the ordinary operation of laceration of the capsule, has resorted to the so-called posterior discission, in which the Graefe knife is passed through the sclera about eight millimeters behind the corneo-scleral junction. Recently

Edward Jackson, arguing that the proper division of the membrane which remains after the extraction of cataract requires the longest possible sweep of the cutting edge of the instrument, advocates the entrance of the knife-needle through the limbus. He also believes that this method lessens the chance of infection. The writer uses Knapp's knife-needle with entire satisfaction; sometimes, when the membrane is thick, he has practised with a modified Hays knife-needle the so-called V-shaped iridotomy, as described by Dr. Lewis Ziegler, of Philadelphia.

The ordinary methods of sterilization of instruments have not been greatly modified, and boiling water continues to hold its very proper preeminent place. It is possible that the recent suggestion made by E. A. de Schweinitz, of Washington, to utilize the vapor of formaldehyde for the purpose of sterilizing ophthalmic instruments, will prove to be valuable. Certainly the method would be a most convenient one.

It is so well known that neither irrigation nor the instillation of germicides produces sterility of the conjunctiva, that surgeons should strive, and do strive (to quote Knapp), to change the conjunctiva, if irritated or congested, into a pale, shining membrane by the simplest regimen. This regimen means that for some days preceding the operation the eye should be protected from anything which may produce hyperemia of the conjunctival vessels, because, as Randolph has expressed it, bacteria ordinarily non-pathogenic (and the normal conjunctiva always contains bacteria) may become harmful under certain favoring conditions, such as bruising the tissues by instruments, or irritating them with chemical substances. Whether all surgeons would be willing to follow Randolph in his advice to abandon conjunctival irrigation entirely is doubtful. Flushing the conjunctival cul-de-sac with a non-irritating fluid like sterilized salt solution immediately preceding the operation can at least do no harm in the sense of bruising the tissues, and may wash away irritating and contaminating secretions, and even, as has been experimentally shown, reduce the number and perhaps the vitality of the organisms which are present.

The evident conclusion of the matter is that strong germicidal solutions should not be used in the conjunctival cul-de-sac immediately preceding a cataract extraction, or after the corneal section; and to quote Randolph once more, in operating upon the normal conjunctiva, as in cataract extraction, the

surgeon would do well to consider the subject of antiseptics and asepsis chiefly in connection with hands, instruments, cocaine, and atropine. When the conjunctiva is not normal, as, for example, in cases of chronic conjunctivitis, lacrimal conjunctivitis associated with disease of the tear passages, blepharo-conjunctivitis, etc., methods of antiseptics necessarily must be more vigorous, or rather operation must be deferred until the affected areas are brought into a reasonable state of health. It seems to the writer very essential in all of these cases to pay strict attention to the preliminary treatment of the rhino-pharynx, from which, no doubt, many cases of infection have arisen.

#### PROPER PREPARATION OF THE YELLOW OXIDE OF MERCURY OINTMENT.

T. E. MITCHELL writes upon this subject in the *Ophthalmic Record* for February, 1898. After referring to the very valuable suggestions of Drs. Babcock and Keiper, in the August and September numbers respectively of the *Record*, in regard to the proper way of preparing the yellow oxide of mercury ointment for use in ophthalmological practise, the writer says he desires to say that no matter how much time and care are consumed in mixing the powder and the vaselin if no other agent is added, minute particles of the mercury will remain and hence defeat the desire to have it uniformly distributed throughout the vehicle. This obstacle can be easily overcome by observing the following instructions in the preparation of this time-honored and valuable therapeutic agent: To the required amount of powder in an impalpable form on a clean glass or porcelain slab add a few drops of any bland non-irritating fixed oil and mix well with a clean spatula; to this slowly add the necessary petrolatum, and for reasons well known to chemical law the powder is so far reduced by the oil that it is evenly incorporated in the vaselin.

The following prescription, which is a favorite one with the author, in the hands of a competent pharmacist will be entirely satisfactory:

℞ Olei ricini, gtt. iv;  
Hydrarg. oxid. flav., gr. iij.

Misce et ad

    Petrolati, ʒ ij-iv.

Misce ft. unguent.

Of course the ointment after all is only a mixture, but the mass is so thoroughly homo-

geneous that not until it is kept for a long while will the mercury gravitate to the bottom.

The author states that he is indebted for the above information to his prescriptionist, Dr. J. P. Turner, ex-president of the Georgia Pharmaceutical Association, and member of the Georgia State Board of Pharmacy.

#### THE TREATMENT OF ASPHYXIA NEONATORUM BY THE HYPODERMIC INJECTION OF STRYCHNINE.

FRY in the *American Journal of Obstetrics* for April, 1898, writes on this topic. In the course of his article he points out that under normal conditions the birth of the infant is quickly followed by respiratory efforts, the contact of the air exciting the reflexes. If such be not the case, evidence is soon apparent of non-oxygenation of the blood. The excess of carbonic acid in the blood then excites the respiratory center in the medulla, and inspiration takes place. If, on the other hand, the respiratory center fails to respond, the cord should be cut and a little blood permitted to escape. The infant should be suspended for a moment by the heels to facilitate the gravitation of mucus from the throat and trachea. The finger passed quickly into the pharynx removes the secretion and excites respiratory effort. The cutaneous reflexes may next be excited by slapping the surface with the palm of the hand or a wet towel, sprinkling with cold water, or pouring ether upon the chest. Immersion alternately into hot and cold water is a good method. The asphyxia persisting, some form of artificial respiration may be resorted to. Schultze's is most efficient, as it aids the expulsion of the fluids from the air-passages by gravitation and expression, as well as produces inspiratory and expiratory movements. If success does not soon reward the efforts it should not be continued too long, as it is a rough method at best. The hypodermic injection of fifteen minims of whiskey acts as a powerful excitant and has given the writer most gratifying results. During the past few years it has given success without other treatment in a number of cases of this form of asphyxia, both in private and hospital practise. In several of the cases the more serious stage of asphyxia had been reached. He believes the credit of this treatment belongs to Dr. Bedford Brown, of Alexandria, Va.; at least he first called attention to it so far as the writer is aware.

If the mild type of asphyxia does not yield to the above treatment or some of its modifications, the more serious form (the pallid) supervenes. The line of treatment should now be modified to meet the changed conditions. The persistence of vigorous efforts to excite artificial respiration will only act injuriously upon the heart and stop its enfeebled action.

An infant born with the pallid form should, contrary to the former advice, be permitted to remain undisturbed in its placental attachment so long as any pulsation of the cord is apparent. It should be suspended by the heels for the twofold purpose of clearing the throat and upper air-passages of mucus and assisting by gravitation to overcome cerebral anemia.

From this point, as well as from the unrelieved livid form, already considered, the infant must be treated as if it were in a condition of shock, which indeed is the case. Rough measures will only extinguish the spark of life.

The indications are: First, to apply external heat. This is best done by immersion in water at a temperature of 100° F. Second, stimulate the respiratory center, the flagging circulation, the paralyzed muscular system, and abolished reflexes.

This brings up the recommendation of strychnine hypodermically to fulfil the indications. It is our most powerful remedy in surgical shock; it should be equally valuable in the grave form of asphyxia neonatorum. Its use for such purpose was suggested to the writer's mind eighteen months ago, and the result has more than met his expectations. The amount of the drug administered is  $\frac{1}{10}$  grain. On one occasion a nurse gave by mistake  $\frac{1}{10}$  grain to a premature infant delivered by version in a case of placenta previa. The infant was soon relieved of the asphyxia, but had pronounced spasmodic twitchings of the muscles, and died on the second day. It is uncertain whether the fatal termination was due to the drug, but the infant showed the toxic effect of strychnine in a decided manner.

After the administration of the strychnine accessory methods of treatment may be employed. Artificial respiration may be carried on while the child is in the hot bath. Sylvester's or Dew's method answers best under these circumstances. Jacobi has advised the rectal injection of hot water, and Grandin of hot normal salt solution. The latter might be given more effectively by injection into the subcutaneous tissue or directly into the vein.

**MERCURIUS IODIDE POISONING RESULTING FROM THE USE OF IODOFORM AS A SURGICAL DRESSING AND CALOMEL INTERNALLY.**

The *American Journal of Obstetrics* for April, 1898, has an article on this subject by SIMPSON, in which he details a case of poisoning from the causes named in the title. He thinks the following combination of events is worthy of note:

1. The use of an extensive intraperitoneal dressing of iodoform gauze representing about half an ounce of iodoform.

2. The development of symptoms of iodoform intoxication, showing the absorption of that drug.

3. The administration, forty-eight hours after operation, of seven grains of calomel.

4. The occurrence of numerous bloody mucous stools at frequent intervals and accompanied by tenesmus.

5. The subsequent use of calomel without undue effect, showing absence of idiosyncrasy to that drug.

The question naturally arises, Was there any causal relation between these phenomena? The following facts led the writer to believe that such was the case, and he has subsequently found no reason to change that opinion: The absorption of iodoform as a dressing begins at once and is most rapid from a peritoneal surface, less so from other surfaces. It continues as long as iodoform is in contact with the absorbing surface. Elimination begins within an hour, and its products—viz., iodide and iodate of sodium—can be detected in all the secretions. Calomel is likewise rapidly absorbed, and elimination by all the secretions begins promptly. Hence, if the two are being absorbed at the same time, they must be carried by the same media and must come in contact within the tissues and in the reservoirs containing the secretions. When calomel is added to sputum, urine, or feces containing the products of elimination of iodoform, yellow iodide of mercury is formed. In this case, granted the elimination of sodium iodide and iodate by intestinal secretions extending over a period of forty-eight hours; granted the retention of these products in the intestinal canal (for no movement had occurred and elimination is not complete for three days at least), together with the administration of seven grains of calomel by mouth, and the conclusions that the two drugs would come in contact and that the yellow iodide of mercury would result may be inferred.

Add to that the fact that characteristic symptoms of the drug were marked, and the conclusions are confirmed. The facts as above given justify the premises, and the conclusions are legitimate.

In addition to the above facts experimental evidence was sought, but lack of facilities for accurate observation rendered the results of little scientific value; hence only a brief summary is given. The first experiments were made in November, 1896; others in November, 1897. Eleven guinea-pigs were used.

*Group A.*—Five pigs received one grain iodoform hypodermically, and one grain calomel by mouth twenty-four hours later. Four died within twelve hours. Post-mortem examination showed violent colitis with extensive ulceration; small intestine slightly inflamed. Other pig killed; colitis, but not so violent.

*Group B.*—Three pigs given one grain iodoform; no deaths. Two killed thirty-six hours later. In one, whole intestine normal. The other had had one grain iodoform and one-sixteenth grain calomel five days previously; few small old ulcers in colon.

*Group C.*—Three pigs were given one grain calomel each by mouth. Two had had one grain iodoform each five days previously. These two killed at end of twelve hours; colitis and enteritis, but neither so marked as in Group A. Other pig died at end of a week; no post-mortem.

The experiments of M. Rummo and others, showing that iodoform is eliminated slowly, render it possible, at least, that yellow iodide of mercury might have been produced in Group C. Further observations as to the effect of these drugs, separately and combined, will be interesting and of practical value.

The absence of literature on this subject opens an interesting field for speculation. Is this form of poisoning rare? The common practise of using extensive iodoform dressings and of using calomel as a laxative following operation renders it likely that numerous opportunities are afforded for the reaction which results in the production of the yellow iodide of mercury. Has it been found by experience that small doses of calomel suffice, as a rule, to cause free movements, and hence small doses are given? May not this observation have been based upon the effects of the more powerful drug? Does not the small amount of calomel used limit the amount of the yellow iodide of mer-

cury produced, thereby lessening the probability of serious results? Is it not possible that in some cases, with mild symptoms of iodoform intoxication accompanied by slight enteric irritation following the use of small doses of calomel, the irritation has been attributed to the iodoform in compliance with the classification of Dr. Schede, of Hamburg, rather than to its true cause, the yellow iodide of mercury? Has it at times been attributed to an irritating enema? Has it ever been noted without an attempt at explanation? A satisfactory solution to these questions is earnestly to be desired.

[We doubt if enough yellow iodide of mercury could be formed in this manner to produce the symptoms described.—ED.]

---

#### THE INJECTION OF ARTIFICIAL SERUM AS A METHOD OF PREVENTING DEATH FROM EXTENSIVE BURNS.

The serum employed by TOMASOLI (*Monatshfte für Praktische Dermatologie*, Bd. xxv, No. 2) is a solution of sodium chloride and sodium bicarbonate. In a sixty-year-old woman with an extensive burn of the third degree, injections of from three hundred to one thousand grammes of serum in three days did not prevent a lethal termination. In a second case, a young man twenty years of age, with burns of the first, second and third degrees, covering the entire right side of the chest, the right axillary space, the whole of the right arm, shoulder, back, and buttock, recovery took place. The patient received daily from March 13 until April 6 serum injections of from two hundred and fifty to five hundred grammes each, and on May 3 left the clinic in an improved condition.

Tomasoli experimented on animals. The hind legs of rabbits and dogs were burned or scalded by being immersed in water the temperature of which was gradually raised to 70° C. All animals burned in this manner died within thirty-six or forty-eight hours. Six rabbits of the same weight as those employed for comparison received injections of fifty grammes of artificial serum immediately after being burned. Four of them died within the first twenty-four hours; the remaining two continued to live. Ten dogs, burned as has been described, were daily injected with from one hundred and fifty to two hundred grammes of artificial serum. Only two of them died, and in these death occurred a few

hours after they were scalded. All test animals that did not receive serum injections died within the first two days, notwithstanding the fact that they were selected and kept in a practically identical condition with the other cases. The writer also states that if serum be taken from one of these scalded dogs (not treated by saline injection), or if from the flesh of one of these animals an extract be made, and a definite quantity of this serum or extract proportionate to the weight of the animal experimented upon be injected into a healthy dog, the dog will die. On the other hand, if a dog in practically the same condition as the other one be injected with artificial serum immediately after receiving a lethal dose of the extract, this dog will not die.—*Medical Record*, Jan. 29, 1898.

*THE DANGERS FOLLOWING THE USE OF  
IODIZED PREPARATIONS IN TUBER-  
CULOUS SUBJECTS.*

Among the symptoms of iodism, remarks a writer in the February number of *La Clinique*, there are some that are localized in the lungs, and manifest themselves by cough with muco-serous sputum and by pains in the pleura. An abundant transudation of serosity has also been observed in the lungs of dogs which had been subjected to subcutaneous injections of iodine and an iodide in solution, according to Zeissl. These facts have led to the supposition that in certain cases of pulmonary tuberculosis the administration of the iodides may cause in the lungs a congestion and a process of softening which is very injurious to the patient.

Vitvitsky, of Kharkhow, observed a case which was very conclusive in this respect. The patient was a woman twenty years old who suffered from a cough with a prickling sensation in the throat and pain on deglutition; at the apices there were suspicious stethoscopic signs. However, the patient had no fever and her general health was excellent. A laryngoscopic examination revealed an intense congestion of the larynx and ulcerations of the vocal cords. As there was cause to suspect a syphilitic origin for this affection, ammonium iodide was prescribed in amounts of thirty grains a day. After eight days of this treatment the patient's condition was manifestly aggravated; the cough had increased, the temperature had become febrile in character, râles and a bronchial souffle were heard in the apices,

Koch's bacilli were found in the sputum, which before had been free from them, and galloping phthisis set in which terminated very soon in death.—*New York Medical Journal*, March 5, 1898.

---

*ON THE NATURE AND PREVENTION OF  
PUERPERAL FEVER.*

The *Birmingham Medical Review* for February, 1898, contains an article by THOMAS WILSON on this subject. He remarks that in women who have pathological discharges, preliminary treatment by warm vaginal douches during the two or three weeks before labor is of great importance. During the same time all women, but especially those just referred to, should be instructed to employ more than the usual care to secure the daily thorough cleansing of the external organs; for this purpose soap and water are the best applications. It may be observed that sponge, though generally in use, is the worst possible material with which to mechanically cleanse these parts; it soon gets full of foul putrefying dirt, which cannot be thoroughly got rid of. The use of sponges in pudendal ablutions should therefore be abolished, and in their stead pads of wool or tow, which can be burnt, should be recommended.

As soon as labor begins, the woman should be carefully prepared as if for an operation. If seen early enough an enema, which may consist of two pints of warm soap-suds, should be administered, so as to secure the thorough evacuation of the lower bowel. This proceeding not only has a marked effect in favoring the due and normal action of the uterus, but is also of great importance in preventing fouling of the vulva and perineum, and perhaps infection of a perineal tear later in labor. When the enema has acted, the nurse, or if necessary the medical attendant, should cleanse the vulva as carefully as if it were going to be operated upon. For this purpose it is desirable first to cut short the hair of the labia with scissors; the whole region, including the mons veneris and the inside of the thighs, is then well scrubbed with hot water and soap and a brush for three measured minutes; then with a wool swab, ether, spirit, or turpentine should be well rubbed into the same parts; and finally the chosen antiseptic lotion, 1-in-2000 mercuric chloride or whatever may be preferred, should also be well rubbed in with a swab. The last two pro-

ceedings should have three minutes divided between them. In all these proceedings great care should be taken not to miss any of the crevices and depressions which abound in the vulva, and the lower and easily accessible portion of the vagina should be attended to at the same time. After the enema and the cleansing the woman should put on clean clothes—those next the skin should be fresh from the laundry, and over these should be clean petticoats and dressing-gown, for as long as she is to walk about the room.

Among poorer women it is usual for an old and often abominably dirty skirt to be put on for the labor; it is perhaps superfluous to remark that it is part of our duty to bring about the abolition of this disgusting and dangerous practise. At no other time of her life is it so necessary for a woman to be clean in her own person and in all her surroundings as it is in childbed.

The important points in the second stage of labor are in the first place that it should neither be hurried nor unduly prolonged; and in the second place the proper management of the perineum. A vaginal examination is necessary at the beginning of this stage when the membranes rupture, and if all be found normal, then the course of labor may be sufficiently observed by palpating the abdomen from time to time, by watching the duration of the interval between the pains, and by observing the maternal pulse between the pains. The timely, but not too timely, use of the forceps in careful and skilled hands is important in many cases in preventing the exhaustion of the patient, which is conducive to infection. When the head comes down on to the perineum, this must be supported so as to prevent, as far as possible, laceration. In doing this a clean napkin should be placed over the perineum, to prevent the hand from contamination. At the end of the second stage the perineum should be carefully examined, and any tear that is more than superficial immediately sutured. For the purpose of this suture the best material is silkworm-gut, a few strands of which, together with a handled needle, should be found in every midwifery bag; catgut is of no use at all, and silk, on account of its absorbent properties, is much inferior to the fishing-gut. The suture of these tears where they are at all extensive is of the utmost importance in preventing both immediate infection and later pelvic suffering of various kinds. The writer states that he has been told in all good faith by medical brethren

that they have never met with a perineal tear in all their extensive midwifery practise. These gentlemen he recommends, in every case, to examine the perineum carefully at the conclusion of the second stage; they have been deceiving themselves.

In the third stage of labor our efforts must be directed towards insuring good and complete contraction of the uterus; the writer's opinion is that this is best insured by what is known as Cr  d  's method; at any rate it is necessary to secure good contraction in order that there may be no retention of clots. The placenta and membranes also must be examined after their expulsion to see that no portion is left behind in the uterus, to undergo putrefaction later on. At the conclusion of this stage, in cases where numerous internal examinations or where operative measures have been undertaken, an antiseptic douche should be given; in ordinary labors, as has already been said, this is superfluous. Finally an abdominal binder is applied, and is of use, from our present point of view, in keeping up intra-abdominal pressure and in preventing a negative pressure in the vagina, which will lead to the retention of discharges; such a retention would be most favorable to the growth of any micro-organisms that might be present; the discharges of albuminous material form a good medium, and the other conditions, moisture and a temperature of 99   F., easily lead to a flourishing cultivation.

In the puerperium the greatest care should be taken to insure the cleanliness of the external organs; these should be carefully cleansed twice daily with a warm solution of boracic acid, iodine, or any other antiseptic which may be chosen, used by means of a swab of wool, which is afterwards burnt. The same toilet is necessary after each evacuation of the bladder or rectum. In the intervals a pad of absorbent wool is the best dressing for the parts. The routine use of the douche during the puerperium is unnecessary and sometimes harmful; syringing should only be ordered in the classes of cases which have been already enumerated; the best material is a solution of iodine of the strength of a drachm of the liniment to the pint of water, and the douches should be continued for at least ten or twelve days. In every case where injections are considered necessary, they should be administered by the medical attendant himself, unless he can absolutely rely on the care and efficiency of the nurse.

Such is an outline of the principal points

which are of importance in preventing the infection of parturient women. The writer admits that there is nothing new in his remarks, and that the ground has been gone over many times before. The stubborn fact remains, however, that there are apparently still as many cases of puerperal infection among the general population now as fifty years ago, and so long as this is a fact he holds it to be the duty of members of societies to consider from time to time the principles and the practise, the science and the art, on which reliance is placed for the prevention of the disease. Towards this duty individuals may be impelled but feebly by the consideration of mere statistics; a death in one's own practise, very likely in a young and blooming primipara in the full vigor of womanhood, acts as a powerful incentive. How much more terrible a goad is an epidemic! It was the writer's lot in 1882 to be a resident pupil at a well known lying-in hospital at a time when an epidemic broke out, the last that has raged within its walls. Within ten days sixteen women, at least nine of them primiparæ, were attacked; twelve of the sixteen died, all of them in from five to twelve days after delivery. No words can describe the effect which this terrible visitation produced upon the pupils; the feeling of utter helplessness and hopelessness in the presence of the established disease can never be effaced from the writer's memory.

#### GASTRECTOMY.

The operation of the removal of the entire stomach, and anastomosis between the lower end of the esophagus and the duodenum, has been for the first time successfully performed in this country by Dr. Charles Brooks Brigham, of San Francisco, and the account of the case is published in the *Boston Medical and Surgical Journal* of May 5, 1898. As a surgical achievement this operation certainly takes rank as an operation of the first magnitude.

The fact that after the removal of the stomach, in animals of strong vitality, the nutrition might be maintained by the compensatory overactivity of the intestines was demonstrated by Czerny in 1876.

In 1895, Schuchardt, of Stettin, removed the entire stomach, except a very small portion at the cardiac end, and the patient lived a life of comfort and activity for two and a half years after the operation.

In September, 1897, Schlatter, of Zurich,

removed the entire stomach from a female patient, for cancer, and performed anastomosis between the esophagus and a loop of the upper portion of the jejunum, sewing up the divided distal end of the duodenum. The patient is now well and strong.

The success of Schlatter's case has undoubtedly inspired with emulation surgeons in all parts of the world, but the case of Dr. Brigham is, as far as we can learn, the first successful result reported.

Dr. Brigham's operation differs from that performed by Schlatter in that he was able to unite the lower end of the esophagus directly with the cut end of the duodenum, thus saving time, an element which is of paramount importance in so extensive an operation, and one involving so great danger from surgical shock. The good judgment of Dr. Brigham in recognizing that his patient would not bear the more time-consuming method of anastomosis by suture, and resorting to the Murphy button, was amply vindicated by the result. The disadvantages of the button as compared with suture were recognized by Dr. Brigham, as he states in his paper, but they were outweighed by the paramount necessity of saving time, and were not sufficient to prevent success.

Dr. Brigham's case is of great interest, as showing that in certain cases it is possible to join the duodenum to the intestine without undue tension. In the not infrequent cases in which the duodenum is lower than the normal position this would probably be impossible, and the procedure adopted by Schlatter of uniting the lower end of the esophagus to a loop of jejunum would be the only resort.

It is interesting to note from Dr. Brigham's account that the constitution, mental disposition and previous habits of diet of the patient were most favorable to the success of the operation. Of a quiet disposition and simple tastes, accustomed since the loss of her teeth to a liquid diet, such as she must of a necessity subsist on for a time after the removal of the stomach, she presented an ideal subject for the operation, except for one circumstance, the thickness of her adipose layer. Even this, although it necessitated a longer incision, may not have been entirely a disadvantage, as it must have tended to enable her to withstand low diet better than would have been possible for a thin, cachectic patient.

It is impossible in this brief notice to allude to all the points of interest in matters

of surgical technique, such as the fact mentioned that unless the left lobe of the liver were hypertrophied the operator would find plenty of room for manipulation in the sub-diaphragmatic space, or to the physiological points with regard to diet, etc., which are illustrated in Dr. Brigham's careful account of his remarkably successful case.

A brief consideration, however, will justify the deduction that cases suited to the operation are rare. It is certainly an uncommon experience for a surgeon to meet with a case of cancer of the stomach in as good physical condition as was Dr. Brigham's case. The pale, thin, worn, cachectic victims of this disease are seldom in a condition to withstand so formidable an operative procedure. Even in this case the operator was compelled to hasten his operation by employing a method of anastomosis which he would not otherwise have chosen.

Schlatter and Brigham have shown, however, that there exists a certain (probably small) proportion of cases in which resort to this most radical surgical procedure may for a time at least rescue the patient.

The time (two and a half years) which Schuchardt's patient lived after the operation proves that the prolongation of life may be by no means inconsiderable.—Editorial in the *Boston Medical and Surgical Journal*, May 5, 1898.

---

**CASE OF REMOVAL OF THE ENTIRE STOMACH FOR CARCINOMA; SUCCESSFUL ESOPHAGO-DUODENOSTOMY; RECOVERY.**

In the *Boston Medical and Surgical Journal* of May 5, 1898, BRIGHAM reports an extraordinary case. He begins by telling us that the operation for removal of the stomach belongs to middle or old age, the disease necessitating it occurring at these periods. Where there are no adhesions the operation is not very difficult; with ordinary care hemorrhage is not likely to occur. The effect of surgical shock upon the patient is most to be feared, and should be guarded against by heat, stimulants, and quick work in operating. The Murphy button saves much time and has proved of great service in the present case. It is not always possible to do esophago-duodenostomy, and the button would do as well in esophago-enterostomy, for it could be applied where it would be impossible to make a sound suture, as in cases where the esophageal end is very

short. If, however, careful sewing could be done quickly and accurately over some form of tube that could be pulled out through the mouth when the sutures were placed, it would save considerable worry to the patient and surgeon. The cases could be well imagined which would be difficult to nourish for two weeks through the openings of a No. 3 button. Besides the impossibility of taking much nourishment at a time, there is the difficulty of swallowing, which the presence of the button in the esophagus causes by reflex action. This reflex action was very slightly marked in this patient; but with a more sensitive nervous system it might be enough to prevent swallowing sufficient nourishment to sustain life, especially if added to this it became impossible to retain nutritive enemata.

It would seem easy, from what is seen in anatomical plates, to join the duodenum with the esophagus, for apparently they are on the same plane; but in reality the esophageal orifice is on a higher plane and behind the pyloric orifice. If the duodenum is not bound down by adhesions, it can be approximated without much tension to within an inch of the diaphragm, allowing the abdominal part of the esophagus to be only two centimeters in length, which is Cruveilhier's estimate. There is even then room to place purse-string suture and apply the Murphy button. It would seem that tension on the elastic tissue of the abdominal esophagus would easily give an increased length; it does stretch to a certain point, but is disappointing and much more limited than one would suppose. From the experience which this case gives, the author thinks it would be easier to tear the esophagus than to pull it down from its opening in the diaphragm. It may have been that the esophageal clamp interfered with its elasticity, but it seemed at the time of the operation as if the stretching could be accomplished much more easily sidewise than lengthwise. A slight gain in the length of the esophagus can be made if the clamp is applied vertically instead of sideways; there is thus less chance of making an oblique cut in the division of the esophagus. Unless there is enlargement of the left lobe of the liver, there is much more room to work in than would be supposed, especially if the abdominal incision is a large one. In fat patients the incision can hardly be less than seven inches in length, and then there is no room to spare.

In the treatment of this case no attempt

had been made to predigest the nourishment which was given to the patient. The precaution was taken, however, to supply easily digested food; and when meat was allowed it was cut in very small pieces. The food was taken slowly, whether liquid or solid. It is no hardship for the patient to live on simple food, for she has done so all her life; and especially as age has advanced she has been obliged to eat food that required the least chewing. The food was given of medium temperature; water was taken as it came from the pipe and wine as it stood in the room; iced cream, of which the patient was particularly fond, was taken slowly, so that it dissolved in the mouth before it was swallowed. At first everything was too salt; as the patient got well, she wished salt on both eggs and oysters. The amount of flatus in the bowels was enough to cause pain only a few times in the early part of her illness. The urine has been normal throughout. Never since the operation has any undigested food been seen in the movements from the bowels, and for the most part these have been wholly or partly formed. The patient has vomited but a few times since the operation; twice after etherizations, twice after some laxative had been given, once after the button left its place, and twice after coughing—not more than six ounces at any one time, generally much less. On three or four occasions a mouthful of food would be regurgitated—an oyster, some shreds of meat, or a few teaspoonfuls of coffee. As a usual thing the food was well retained and well digested. Milk, which would sustain most patients under such circumstances, was not liked, and an important food was thus unavailable. The patient's skin is in a natural condition, without any dryness; this may be due to the thorough washing which the entire body has had daily since the operation. The symptom which gave the most anxiety after the operation was the restlessness, which was unusually marked. This was without doubt the result of the surgical shock, which was caused by the removal of so important an organ as the stomach, and the interfering with its vessels and nerves.

The season of the year in California, with mild, sunny days, and the careful and constant nursing, are among the factors which made the operation a success. The age of the patient counted for something also; the effects of the change of life had long passed by, and there had been for many years an even condition of good health. Many old

people can stand in a surgical point of view much more than is generally supposed. The patient was not worried about herself. All she wished for was to be restored to health; how this was to be accomplished she never asked, and to this day she does not know that her stomach has been removed. She has a fine color; complains of nothing so far as the functions of her body go; eats whatever she wishes; has no pain whatever; is of a very cheerful disposition. She is out-of-doors most of the day from ten till five o'clock, taking occasional walks around the hospital grounds; her temperature and pulse are normal; she sleeps well without an opiate. Although she has food every three hours, she feels quite hungry at times, and feels that she could eat twice as much as is given to her. She is gaining in weight; and her general condition at the present time (April 14), seven weeks after the operation, is satisfactory in every respect.

---

*HYDRAULIC PRESSURE IN GENITO-  
URINARY PRACTISE, ESPECIALLY  
IN CONTRACTION OF THE  
BLADDER.*

H. H. YOUNG writes on this subject in the *Johns Hopkins Hospital Bulletin* for May, 1898. He says that the necessary apparatus consists in an ordinary fountain syringe with tube about eight feet long, a conical nozzle which will fit tightly into the meatus, but not injure the urethral mucous membrane, and a pole or other apparatus by which the irrigating bag may be elevated or lowered as desired (a nail in the wall will answer the purpose).

The patient should lie on his back on a bed or couch which is covered by an oilcloth, with a basin between his legs. The operator stands on the right side, takes the penis between thumb and finger of his left hand, the sterile nozzle in his right. The foreskin is retracted, and with the bag elevated three or four feet, the fluid is allowed to play upon the glans penis and meatus. The urethra is alternately distended with fluid and emptied to clean the anterior urethra, and the nozzle is then crowded tightly into the meatus, the bag raised to an elevation of about seven feet, the penis being held just back of the corona so as not to compress the urethra, as Valentine's complicated nozzle and stop-cock are unnecessary.

The urethra will soon become ballooned out, and for a time the fluid will be seen to

stop flowing through the nozzle, but very soon the sphincters will give way and a "purling" sensation be conveyed to the hand by the fluid flowing into the bladder. After the sphincters are overcome very little pressure is required to force the fluid into the bladder, and it is best to lower to a height of four and a half or five feet, as too much pressure may produce spasm of the bladder and prevent dilatation.

As the fluid flows gently into the bladder the patient will soon experience a sense of fullness and then of gradually increasing pain.

In cases of contracture where systematic dilatation is to be adopted, the distention must be continued until the pain is very considerable and the patient tells you he cannot "stand any more." The tube is then squeezed to cut off the flow, the nozzle withdrawn, and the fluid, which is ejected with considerable force, caught in a half-liter glass or other receptacle.

The operation is repeated until the quart of fluid has been used.

The procedure is so simple that patients soon learn to conduct their own treatment. They always become intensely interested in the progress of the dilatation and vie with each other as to the amount of fluid and urine held.

Very bland fluids are the most satisfactory in the majority of cases. Best of all is Thomson's fluid, which is composed of borax, glycerin, sodium chloride, and water. It is the most soothing preparation for any inflamed mucous membrane that we know of. Boric acid in two-per-cent. solution is excellent.

A very good plan is to use occasionally a stronger antiseptic fluid, such as silver nitrate half a grain to one ounce, or bichloride of mercury 1 to 150,000 solution, up to 1 to 50,000. When four or five irrigations are given daily it is well to use one of these once daily, followed by a weaker solution.

Silver nitrate is especially effective where an ulcerative condition of the mucous membrane exists.

Boric acid or salol in five- or ten-grain doses may be given if the urine is alkaline, and citrate of potassium when hyperacidity causes much burning.

The reaction of the urine in cystitis depends almost entirely on the character of bacterium present, and it is irrational to attempt to change its reaction by internal drugs.

As shown in his cases, the urine becomes acid as the bladder inflammation begins to subside.

As in inflammation elsewhere, there is at first a proliferation and infiltration of round cells, which as time goes on become more and more spindle-shaped and finally form fibrous tissue. Ulcerative areas in the mucous membrane also lead to the production of scar tissue, with its inherent tendency to contract. The inflamed mucous membrane, irritated by the presence of urine, expels it frequently; the bladder is therefore never fully distended and offers no resistance to the contraction of the scar tissue, and contracture results. In this process the blood-supply of mucosa is greatly interfered with, and the mucous membrane is thrown into folds and pockets which retain the purulent exudate, thus adding to the inflammation.

The effect of forced dilatation with fluids is probably as follows:

Irritating secretions are washed away.

The individual bundles of fibrous tissue are separated or loosened, allowing increased vascularity.

Folds and pockets of mucous membrane are smoothed out; ulcers are stretched and cracked, allowing new blood-vessels to grow out, in precisely the same way that leg ulcers are cured by scarification; the bladder muscle is exercised and the tone is improved; the mucous membrane, cleaned, stretched, and with increased vascularity, is given a chance to throw off the inflammation.

In a normal empty bladder the epithelium is several layers thick, but when fully distended is said to be only one layer thick. Dilatation of an inflamed bladder therefore gives the antiseptic fluids a better chance to reach the disease.

A review of the author's cases shows:

That it is possible to restore the capacity of a bladder contracted by chronic inflammation of the worst character by systematic distention by hydraulic pressure.

That such dilatation has a most beneficial effect on the vesical inflammation and muscular tonic.

That the number of urinations daily may thus be greatly diminished.

That no ill effects are produced by considerable hydraulic pressure, and there is no danger of infecting the kidney.

One of the most striking features of the treatment is the rapidity with which patients improve. Pain present for years may disappear in a few days, pus and mucus diminish

markedly, and strongly ammoniacal urine becomes acid in a short time.

And yet, says Young, a late text-book on genito-urinary disease says as follows: "The theory that the capacity of an inflamed bladder can be increased by dilatation is contrary to physiology and anatomy. To attempt by forced injections to relieve frequent micturition cannot be too strongly condemned."

#### NEW AND ORIGINAL METHOD OF OSTEOPLASTIC RESECTION OF THE SKULL.

A satisfactory method of osteoplastic resection of the skull has long been desired. BUCHANAN believes, so he tells us in the *Medical Record* of June 4, 1898, that the procedure here described will be found to have advantages over those hitherto employed. Among these may be named the following:

1. It causes very little injury to the bone.
2. It is not attended by jarring or other possible injury to the brain.
3. It is free from danger to the dura mater.
4. It is precise in its results and the flap is capable of any required variation of shape.
5. The bone flap, when returned to place, fits exactly and has no tendency whatever to displacement.
6. It is easy and comparatively rapid of execution, causing no fatigue to the operator.
7. The instruments are simple, inexpensive, not liable to break or get out of order, and are not dependent on a motor of any kind.

The elements of the method are: (1) The selection of a flap suitable to the requirements of the case, usually in the form of a quadrangle, pentagon, or hexagon; (2) incision to the bone on all sides except at the base of the flap; (3) perforation of the cranium at each angle of the incision with a small mastoid trephine; (4) separation of the dura mater from the cranium between the points of perforation; (5) sawing the bone between the perforations with a Gigli-Haertel wire saw, passed between the bone and dura mater from one perforation to the next; and (6) lifting the flap of scalp and bone from the dura mater.

The instruments required are:

1. Those shapes most generally useful for outlining the flaps. These are pentagons or hexagons, usually with sides five centimeters long. These shapes are of aluminum or

double-faced rubber cloth, either material being capable of sterilization without injury.

2. A slightly conical trephine six millimeters in diameter.

3. A dural separator three millimeters wide, blunt extremity slightly wider and thicker, grooved upper surface, very slightly curved from end to end, turning rather abruptly upward at each extremity. The shape is important. The length between the curves at the extremities is five centimeters.

4. Gigli-Haertel wire saws, thirty centimeters long. This is the instrument the use of which distinguishes this procedure from those hitherto proposed.

5. Small blunt hook to lift the loop of the saw from the trephine opening.

6. The bone elevators.

In selecting the shape and direction of the flap, regard should be had for the area it is desired to uncover and the location of the vessels of the scalp entering its base. A distance of five centimeters between openings will usually be found most convenient, although longer intervals may be separated and sawn without trouble. Impromptu and atypical outlines may be used, but ordinarily a set figure, selected beforehand, will be most satisfactory. The pentagon may be made to form several different flaps by using different sides for the base and by reversing the figure.

An incision having been made to the bone along all the sides of the figure laid out except its base, trephine openings are made at each angle in the usual manner. The small size of the trephine renders this a very easy matter. The dural separator is now passed into one of the openings and, by gentle lateral movements, made to separate the dura mater from the skull till its extremity can be seen at the bottom of the adjoining opening.

In case the skull is thick, it may be necessary to chip away, with a chisel, the perpendicular edge of the trephine hole into which the separator enters at that part of its circumference which is opposite the opening toward which it is directed. This allows the separator to enter obliquely to the surface and easily follow the surface of the dura mater. In thin skulls this will be found unnecessary.

When the end of the separator appears at the bottom of the adjoining opening, a wire saw is passed along its groove till the looped extremity of the saw appears at the bottom of the trephine opening, through which it is

drawn with the blunt hook. The handles of the wire saw are then attached and the separator is held in place by an assistant, who at the same time steadies the head. The saw is then made to cut its way out, which it does with surprising ease. Any possible injury to the dura is obviated by retaining the separator in place during the sawing; but no injury has been observed even when the dura has been left unprotected. During the sawing the hands should be kept well apart, for the saw is apt to break if used at an acute angle.

This proceeding is to be repeated with all sides of the flap except the base, which can be sawed nearly through without injury to the overlying flap.

The elevators are used to pry the flap up, and very little force is required to break the unsawed portion at the base.

When the flap is returned, it fits precisely and cannot possibly be displaced. The only loss of bone is at the trephine openings, while between the sawed surfaces a sheet of paper cannot be passed.

It is hoped that an extended clinical trial may prove this method as satisfactory as it has been in numerous experiments on the cadaver.

#### *CUT-THROAT: ITS IMMEDIATE TREATMENT.*

DUNCAN writes on this topic in the *Inter-colonial Medical Journal of Australia* of March 20, 1898. He thinks that the sort of rigid conservatism that has hitherto guarded this particular state, in directing a particular method of procedure, promises soon to be supplanted by a plan more in accordance with modern ideas. That a cut-throat should be dealt with by immediate suturing is largely due to Mr. Morris, the able Middlesex surgeon. It would serve no useful purpose to give the reasons that governed the old-fashioned treatment. The only wonder is that such antiquated ideas should have held their place for so long, and especially during the last few years, when so much surgical enlightenment has prevailed. An excellent opportunity was afforded lately of putting the immediate treatment of cut-throat into practise, and noting the result.

The patient, a blacksmith, a patient of Dr. Lines, of Woodend, inflicted a severe gash on his throat with a dirty pocket-knife when under the influence of drink. The wound in front was slightly below the cricoid cartilage, and practically severed the windpipe, it being

only held together by a small piece behind. Laterally, the wound extended on each side nearly to the carotid sheaths, but not to within a dangerous distance. The patient on admission to the hospital had lost a great quantity of blood, and was a good deal collapsed. He was known to be the subject of chronic alcoholism in its worst form, and was therefore not a very promising patient from a constitutional point of view. The writer assisted Dr. Lines in treating the wound. A stout needle, threaded with strong salmon-gut, was run through the severed windpipe from below upwards. The needle was made to transfix the parts about a quarter of an inch from the severed edges. One median and two lateral sutures were used. On tying the sutures, the severed part came easily into apposition. As an additional security, similar sutures were made to under-run the soft parts, overlying the upper and lower segments. The windpipe was then covered in with the neighboring soft parts, buried sutures of catgut being used for the purpose. The wound was finally closed with stout salmon-gut, and a small drainage tube inserted at the lower angle. The upper two-thirds of the wound healed by first intention, and very slight suppuration occurred at the lower part, not sufficient, indeed, to materially delay the healing of the wound. The patient was discharged at the end of a fortnight with the wound soundly healed.

It is needless to add that every effort was made to render the wound as far as possible aseptic. This was all the more necessary, since the wound was inflicted with a dirty pocket-knife, as already mentioned. It is not to be expected that the results attained in this case would be attainable in all cases, but treatment based on such lines is certainly calculated to yield much better results than by the older and more antiquated methods.

#### *RECENT PROGRESS IN RENAL SURGERY.*

The advances which have been made in recent years in surgery of the brain and the bowel are perhaps the most striking manifestations of the modern progress of surgery, but improvements of at least equal importance have taken place in the methods of surgical treatment of the kidney. In *The Lancet* of April 30 was published the last of the Hunterian Lectures on the "Surgery of the Kidney" which Mr. HENRY MORRIS has recently delivered at the Royal College of Surgeons of England, and every one who has

read these lectures must acknowledge the great importance of the subject with which they deal.

Renal surgery is altogether modern. Abscesses in connection with the kidney had been occasionally incised, but only when they had so closely approached the surface that they were pointing, and the surgeon was doubtless greatly surprised to find that he had operated on a kidney. In the same way, too, renal calculi may have been removed after incision of a presenting pyonephrosis. These cases, however, are really not worthy of being considered cases of renal surgery at all. Further, it is true that in the sixteenth century the practicability of nephrotomy was discussed, but no application of these theoretical possibilities was ever made.

In 1869, Gustav Simon, of Heidelberg, removed a kidney from a woman with great success. This is the first real operation on the kidney. The possibility of life continuing in the absence of one kidney had been amply demonstrated by experiments on animals, but Simon's success was needed to convince surgeons that the same fact was true as regards human beings. The simpler operation of nephrotomy was, however, the renal operation which met with the greatest recognition, and it was performed in no small number of cases for the relief of pyonephrosis, and in a few of these a stone was removed. It was, however, not then recognized that there was an earlier stage than pyonephrosis in which surgical interference might be of advantage.

In 1880 Mr. Morris cut into the apparently healthy kidney of a young woman and removed from it an oxalate of lime calculus. This was indeed a notable advance; it showed most conclusively that a thick layer of renal tissue could be cut through without any fear of uncontrollable or even severe hemorrhage, and that a wound of the kidney substance healed readily and thoroughly. But it showed much more than this: it showed that it was absolutely unnecessary to wait until a renal calculus had led to the complete destruction of a kidney before attempting to remove it, and that it was not only possible but safe to remove a stone from a kidney otherwise equally healthy. The example thus set has been regularly followed and the results have fully justified this alteration in practise. In Mr. Morris' own cases of nephrolithotomy only one death occurred in thirty-four operations. The effect of this change of practise has been great, and as a consequence the operation of nephrolithotomy has largely re-

placed the simpler but less satisfactory nephrotomy in all cases in which the patient has applied for treatment sufficiently early.

Another operation which has done less perhaps than nephrolithotomy in the way of saving life, but quite as much in removing pain and discomfort, is nephropexy, or nephrorrhaphy, as it is frequently called. A movable kidney has but little tendency to shorten life, yet it leads often to much suffering and may entirely incapacitate for any exertion, and in many cases the relief resulting from nephropexy is great and lasting.

The latest development of renal surgery is of especial interest. When a kidney has been exposed by an incision it is occasionally found that the disease with which it is affected is limited to one part of the organ, and in a few cases it has been found possible to remove with success the affected parts only and thus to preserve a portion of an organ which otherwise would have had to be altogether sacrificed.

If the recent advances in the surgery of the kidney have surprised those accustomed to the old order of things, the modern surgery of the ureter excites still more astonishment. Numerous operations are now performed on the ureter, a structure which was quite recently considered to be wholly beyond the possibility of surgical interference. The first and probably the most important operation performed was ureterotomy for calculus, and though the operation is still rare, yet it has been done by several surgeons, and stones have been successfully removed from all parts of the ureter—from the pelvis of the kidney to the opening into the bladder. Strictures of the ureter have been relieved by ureterotomy, and in some cases a portion of the tube has been excised with results which fully justify the operation. Ureteral anastomosis and ureteral grafting have received much attention in consequence of the frequency with which the ureter is involved in the operation of vaginal hysterectomy. Formerly the only hope which could be held out to a patient suffering from a ureteral fistula after such an operation was nephrectomy, but ureteral anastomosis and grafting bid fair to replace entirely this severe procedure. A still more extensive operation on the ureter is excision. It is only called for in cases of wide-spread and persistent diseases, but it has been successfully performed for tuberculosis and other conditions of the ureter.

Another subject considered by Mr. Morris

in his lectures was "obstructive anuria." It is very rarely indeed that both ureters are simultaneously or almost simultaneously blocked by calculi. In most cases one kidney has been destroyed or rendered functionally useless by a stone, and then later, when the other kidney has taken on the double duty, it too has had its ureter blocked by the impaction of renal calculus. The symptoms which follow are identical with those met with after experimental ligation of both ureters in animals, and usually the symptoms which are commonly called "uremic" are absent. The patient survives a few days, perhaps as many as ten, and then dies. The fatal ending is inevitable unless the obstruction is removed. It has taken many years for it to be generally recognized that obstruction of the intestines cannot be cured by the lavish administration of purgatives, and that the obstructing cause must be removed or the bowel opened above the obstruction. In the precisely analogous case of obstructive anuria diuretics and exercise are still only too often relied on for treatment, and the patient is allowed to succumb when an operation would have saved him. It is true that the percentage of spontaneous removal of the obstruction is greater in the case of the ureter than in the case of the intestine, but the principles involved are the same and an operation should be performed as soon as the diagnosis is established.

The lectures were illustrated by an elaborate set of tables of operations on the kidneys which must prove of great value in the preparation of statistics on this subject.—*The Lancet*, May 14, 1898.

A METHOD OF EXPOSING AND OPERATING ON THE KIDNEY WITHOUT DIVISION OF MUSCLES, VESSELS, OR NERVES.

In the London *Lancet* of May 14, 1898, MAYO-ROBSON describes an important method of operating on the kidney, and tells us that his lamented friend, the late Greig Smith, used to insist on the importance of opening the abdomen in the course of the muscular fibers as much as possible so as to avoid the weakness that is apt to follow on division of muscle; but the author can find no evidence in his own writings, nor did he gather in his many conversations with him, that he had conceived the idea of exploring the kidney on this principle. Dr. McBurney's method of

exposing the vermiform appendix, which the author has employed on numerous occasions with great satisfaction, suggested to his mind the possibility of exposing the kidney in a similar manner, and it was not until he had performed a number of operations by the method he is about to describe that his attention was drawn to a paper by Dr. Abbe in the *Transactions of the New York Surgical Society*, in which he describes a case of nephrectomy performed on the same principle. Seeing that the operation is one which from ample experience he has found of great utility in all operations on the kidney, he has no hesitation in describing it and recommending it to the notice of other surgeons.

The incision beginning on the inner side of the anterior superior spine of the ilium is carried backwards obliquely towards the tip of the last rib. The fibers of the external oblique and its aponeurosis are then split and retracted, exposing the internal oblique muscle, the muscular fasciculi of which are split in a line between the ninth costal cartilage and the posterior superior spine of the ilium, in which position they are longer than in front of or behind that line. When the fingers are pushed through the internal oblique to split it the fibers of the transversalis are pierced and can be retracted along with the oblique muscle. A diamond space is thus formed, at the bottom of which is seen the transversalis fascia, which is then incised, exposing the perirenal fat, and on pushing the fingers through this the kidney is easily reached in whatever position it may lie. If needful the whole hand may be introduced into the perirenal space and the kidney can be grasped and freely manipulated, the retractors for the moment being withdrawn. If the vessels are moderately long, and in all cases of movable kidney, the organ may be brought through the wound and explored by incision or by needling, or it may be examined by the selenium screen and the Roentgen rays. Should a calculus be found it can be extracted and the wound sutured before the organ is returned.

After all necessary manipulations on the kidney have been effected, the kidney, if not removed, is replaced, or if not disturbed from its bed is left *in situ*. The cavity is then sponged out, and on withdrawing the retractors the muscles at once fall together and may, if thought desirable, be sutured with two or three interrupted catgut sutures, the skin incision being brought together by interrupted silkworm-gut sutures. As a rule,

not a single ligature is required, as there is no bleeding.

The advantages of this method of exploring the kidney are obvious: (1) There is no division of muscle and therefore no weakening of the abdominal wall immediate or remote. (2) No vessels are divided, thus not only saving time but rendering healing *per primam* more likely. (3) No nerves are severed, and therefore paralysis of the rectus and other muscles is avoided. (4) The operation is done with the patient lying on the back, to the great convenience of the anesthetist, the operator and his assistants, and to the manifest advantage of the patient, who is saved much unnecessary disturbance. (5) The great saving of time as well as the diminution of hemorrhage means lessening of shock, thus rendering operation feasible when it otherwise might be questionable. (6) It is an important fact that diagnosis in kidney cases, especially in renal calculus, is by no means perfect, and if it can be proved that an exploration of the kidney can be done quickly with little or no danger and without any subsequent weakness being left, the physician will be less loath to permit, and the surgeon to perform, an exploratory operation after all other means have been fruitlessly tried. (7) Lastly, after such an operation convalescence is materially shortened, as the patient may be safely allowed to be up at the end of the second week or even earlier, since there is no fear of the wound giving way.

The author takes this opportunity of saying that wherever he can, when operating away from the middle line of the abdomen, he makes use of the principle of splitting instead of dividing muscles—for instance, in gastrotomy, in inguinal colotomy, in typhlotomy, sometimes in cholecystotomy, and nearly always in the removal of the vermiform appendix. He would also point out that if it be found necessary to extend the opening—for instance, in case of operation on the ureter—deeply in the pelvis, it is easily accomplished by departing slightly from the principle here advocated and dividing the deep plane of fibers and further splitting the external oblique towards Poupart's ligament. The internal oblique will then require suturing to bring together the divided edges. In this way the ureter, even to its entrance to the bladder, may be fully exposed to sight as well as touch, as in a case which was witnessed by his colleagues, Mr. Teale and Mr. Ward, who will, he feels sure, bear him out

in his statement as to the efficiency of this method of exploration. He could relate a greater number of cases on which he has operated, but thinks that those he has given will be sufficient to serve as examples.

## Reviews.

---

TWENTIETH CENTURY PRACTICE. An International Encyclopædia of Modern Medical Science. Edited by Thomas L. Stedman, M.D. In 20 volumes. Volume XIV: Infectious Diseases.

This fourteenth volume, which is in size and shape like its predecessors, covers about 600 pages, including the index, opens with an exhaustive article by Forchheimer, of Cincinnati, upon Scarlet Fever, and ends with one by Bruce upon Malta Fever. The index strikes us as being better than that in some of the preceding volumes, in that it is more complete. Dr. Forchheimer's article covers 114 pages and deals with the history, geographical distribution, etiology, bacteriology and symptomatology of this important disease in a manner which is familiar to those who have read Dr. Forchheimer's previous contributions to medical literature.

Dawson Williams, of London, so well known for his editorial work, contributes the next article upon Measles, a considerable portion of which is devoted to the important subject of prophylaxis, and in this connection a copy of a handbill issued by the Glasgow Health Committee is of interest. Dr. Forchheimer also contributes the article upon German Measles, and Dillon Brown, of New York, that upon Chicken-pox.

The article upon Whooping-cough is by Joseph O'Dwyer and N. R. Reed, of New York, and considering the importance of this disease and the fact that it is written of by two men, the discussion is extraordinarily brief, covering less than twenty-three pages, a considerable portion of which is curiously enough devoted to the subject of intubation as a means of relieving the spasm of the glottis. Antipyrin seems to remain the most popular drug in the treatment of this condition.

Cholera Infantum is discussed by Dr. Jacobi, and the article is written in a way which is extremely characteristic. It is hardly necessary to state that this is an authoritative paper upon the subject of which it treats.

Asiatic Cholera is discussed by Theodor Rumpf in an exhaustive article of about

150 pages, with a fairly complete bibliographical list. A considerable portion of this article is devoted to the important subject of treatment. No less an authority than Sir Joseph Fayrer writes upon Dengue, and Sodné, of Rio Janeiro, upon Beriberi. Malarial Fever is discussed by Netter, of Paris, and the concluding article upon Malta Fever is by David Bruce, of the British Army. This volume is one of the best of the series.

A TEXT-BOOK OF DISEASES OF THE KIDNEYS AND GENITO-URINARY ORGANS. By Professor Dr. Paul Fürbringer. Translated by W. H. Gilbert, M.D. In two volumes. Volume II.  
London: H. K. Lewis, 1898.

The first volume of this work was reviewed in 1895, and in the three years which have elapsed since that time we have been wondering when the second part would appear, for much of the value of a work depends upon the promptness with which it is published as a whole; and this second volume is a translation of what its author wrote a number of years ago. Notwithstanding this fact the complete work is to be considered as a first-rate summary of our knowledge of genito-urinary diseases.

The present volume deals with pyelitis, perinephritis, nephrolithiasis, and the various tumors and abnormalities of the kidneys in the first one hundred pages. The next fifty pages are devoted to diseases of the bladder, and the remainder of the volume, which covers about 300 pages, is devoted to diseases of the urethra in the two sexes and to diseases of the genital organs as they are met with in the male. A noteworthy part of the book is the copious references made by the author to standard writers upon the subject with which he deals; and the volume closes with a good bibliography, which covers about twenty-three pages. The index to both volumes is included in this one. Certainly those who have the first volume should possess themselves of the second, for it is larger, better, and more interesting than the first.

ILLUSTRATED SKIN DISEASES. An Atlas and Text-book. With Special Reference to Modern Diagnosis and the Most Approved Methods of Treatment. By William S. Gottheil.

New York: E. B. Treat & Company, 1897.

We are told in the announcement of this pictorial review of skin diseases that it is an attempt to depict on paper and preserve permanently the varied and evanescent forms of skin diseases, and that as photography gives us form but not color, chromolithography has been resorted to to make the study of dis-

eases in text-books more clear. The publishers believe that the strides which have been made in colored photography within the last year or two render it possible to produce a series of lifelike plates. This Atlas is to consist of quarto portfolios, each comprising twenty-five quarto pages of text and four plates, and in addition numerous black and white illustrations. Twelve portfolios will it is expected complete the work, and three of these have so far been published, the first dealing with the Anatomy and Physiology of the Skin; the second with the Therapeutics of the Skin, Classification and Functional Disorders, such as pruritus, hyperidrosis, chromidrosis, and bromidrosis; while the third portfolio deals with Seborrhœa and various other diseases associated with the oily secretions of the skin, and with Erythema, Urticaria, and Purpura.

The text is well printed and the plates have a handsome appearance. The illustrations, made by the Photogravure and Color Company of New York, are unusually good, for they possess that lifelike tint which is so difficult to obtain in works of this character and upon which the diagnosis so largely depends.

The opening article upon the General Therapeutics of Skin Diseases in Portfolio II seems to us well written, and the entire work is worthy of the confidence of the profession.

A MANUAL OF GENERAL PATHOLOGY FOR STUDENTS AND PRACTITIONERS. By Walter Sydney Lazarus-Barlow, B.A., M.D.

Philadelphia: P. Blakiston, Son & Company, 1898.

The author tells us that he has endeavored to fill, in some degree, a lacuna in the modern literature of Pathology, and to those who are familiar with this literature it would seem that there was either no lacuna to fill or that it was so small that a small amount of material would cause it to overflow. On the contrary, the author seems to have found a very large open space which needs to be filled, for his volume is an octavo of nearly 800 pages, fairly closely printed, and supplied with a bibliography at the end of each important chapter. His chief object in writing the volume has been to present the reader with the results of the study of experimental or general pathology which he thinks have not received the attention they deserve. A large amount of information in the volume is taken from Cohnheim's Lectures in General Pathology, and also from the System of Medicine edited by Allbutt.

From what has been said it is evident that this volume is not intended to be a work upon Pathology in the ordinary sense of the word. On the other hand, it is a story of what has been accomplished by pathological research in explaining and amplifying our knowledge in regard to gross pathology. A chapter which has seemed to us of great interest is that devoted to the Pathology of Heat Government, a chapter which in most books upon Pathology is sadly lacking. This chapter is, however, not as thorough as it should be. Naturally such a chapter must deal largely with physiological facts, for the line drawn between heat processes as they occur in disease and in health is, of course, very indistinct.

The book seems to us to be eminently suited to the needs of the physician who desires to keep himself in touch with the modern knowledge of disease, but not to be adapted to the necessities of the undergraduate student.

AN ATLAS AND ABSTRACT OF DISEASES OF THE LARYNX. By Dr. E. Grünwald. Edited by Charles P. Grayson, M.D.  
Philadelphia: W. B. Saunders, 1898.

The editor's preface states that if it is true that "good wine needs no bush," it is certainly true that so good a book as this needs no preface. Unlike other books in this series, it opens with no less than 103 pages of text devoted to the various pathological conditions which are found in the larynx, and this text is followed by forty-five plates and figures which illustrate these conditions. Here again the skill of the Bavarian lithographer is shown in the lifelike portrayal of healthy and diseased tissues. The book is to be highly recommended to those who are interested in laryngology as a specialty or in diseases of this portion of the body in their relation to general medicine.

DISEASES OF THE STOMACH. By Max Einhorn, M.D.  
Second Edition.  
New York: William Wood & Company, 1898.

Within the last few months no less than four volumes devoted to diseases of the stomach by different authors and publishers have been placed upon the American book market, two of them, one by Hemmeter and the other by Van Valzah, appearing for the first time. The others are new editions of older and more familiar works. It will be remembered that Dr. Einhorn has done exceedingly good original work in studying gastric disorders and that he contributed a

valuable article to the Twentieth Century Practice of Medicine upon this subject, an article which was very nearly related in every respect to the first edition of the work now under notice.

The present volume does not materially differ from the first, which appeared a little over a year ago, but few alterations and additions having been made to it. It shows from beginning to end that the author is familiar as an original worker with his subject. It does not profess to be so exhaustive a manual as the three that we have named, but it will give the practical physician pretty much all the information that he needs in this special line of work.

MODERN GYNECOLOGY. A Treatise on Diseases of Women. By Charles Bushong, M.D. Second Edition, Enlarged and Illustrated.  
New York: E. B. Treat & Company, 1898.

The publishers in a note to this book, which is the first text which our eyes meet, inform us that this book is designed to tell the physician "what to do and how to do it," and the editor tells us in his preface, dated May 2, 1898, that he has remodeled the chapter on Neoplasms in the Special Organs of Women, and entirely rewritten that upon Malignant Disease of the Female Genitalia. To those who are not acquainted with the first edition we may state that the volume contains 105 illustrations and 18 chapters, which deal with Examinations, Menstruation and Its Disorders, Diseases of the External and Internal Female Genitalia, Hygiene, Exercise, and Sterility. The volume closes with an appendix describing instruments and office apparatus, which to many practitioners will prove a useful chapter even though it is exceedingly brief. Altogether the volume contains about 400 pages, which are written in an easy, yet concise, manner. It will not be found a complete treatise upon Gynecology. It is rather to gynecology what a book upon minor surgery is to general surgery, and as such it is deserving of confidence.

YELLOW FEVER. Clinical Notes by Just Touatre, M.D.  
Translated by Charles Chassaingnac, M.D.  
New Orleans: *The New Orleans Medical and Surgical Journal*, 1898.

It is explained to us in the translator's note that this volume has not been published in French, but that its author, having a better knowledge of the French language than of English, wrote it in French, and had it translated. The object of the volume is to present in a concise form the author's personal views in regard to this serious malady. For this

reason a description of a number of cases is to be found throughout the text. He asserts that he was one of the first to note the curious difference between the pulse and the temperature in yellow fever, and he believes that the importance and value of this difference are of the highest order in enabling the physician to make a positive diagnosis on the first or second day of the disease. In the seventh chapter, which is devoted to the consideration of the treatment of yellow fever, the author deals first with prophylaxis and then with the ordinary medicinal and hydrotherapeutic measures which he believes are of value. He believes that bicarbonate of sodium is a very useful remedy in this malady, and relies largely upon full draughts of Vichy water in addition to other treatment more commonly described.

**AIX-LA-CHAPELLE AS A HEALTH RESORT.** By a number of German Physicians of Aix-la-Chapelle. Translated by James Donelan, M.D.  
London: J. & A. Churchill, 1892.

Why this book should have been sent to us so long after the date of its publication we do not understand, unless it is in the way of advertising the springs of which it treats. We notice that a complete list of the various physicians practising in Aix-la-Chapelle is enclosed with the volume, and that the list is completed by the names of the German and American dentists who can be consulted. Although it is largely, therefore, in the nature of an advertisement, this book of over 300 pages nevertheless is one of value and interest to those who have occasion to send their patients abroad. The book contains chapters, first, upon the baths themselves, and second, the diseases treated with success by these baths, including gout, rheumatoid arthritis, diseases of the skin, various catarrhal conditions, syphilis, diseases of the nervous system, diseases of the eyes, and chronic metallic poisoning.

**RHEUMATOID ARTHRITIS.** By Gilbert Bannatyne, M.D. F.R.C.P. (Ed.). Illustrated. Second Edition.  
Bristol, England: John Wright & Company, 1898.

As if to emphasize how little we really know about rheumatoid arthritis and kindred lesions, the medical profession is presented from time to time with monographs dealing with this remarkable malady, and after we have read them we are forced to reach the conclusion that but little real advance has been made in our knowledge of its etiology, pathology, and therapeutics. A noticeable thing

about this little book of two hundred pages is the unusually good illustrations, many of which cover an entire page and which show the swellings and other arthritic deformities characteristic of the disease. These are unusually well represented and are taken from life. It is interesting to notice how the fusiform deformities of rheumatoid arthritis may resemble the dactylitis syphilitica of the older writers. Most of the chapters have appended to them brief but apparently valuable bibliographies, and the volume closes with an index of authors and of subjects.

The author endeavors to substantiate his claim that Wohlmann and himself have discovered the micro-organisms which are specific to this disease, and he takes pains to elucidate their life history and peculiarities as worked out by Bloxall. Because of his belief in the bacteriological origin of this disease Dr. Bannatyne is most emphatic in separating senile arthritis from the more general disease rheumatoid arthritis.

**OUTLINES OF PRACTICAL HYGIENE.** By C. Gilman Currier, M.D. Third Edition, Revised and Enlarged.  
New York: E. B. Treat & Company, 1898.

This is a small octavo volume of nearly 500 pages devoted to Hygiene, as its title indicates. It is rather an essay upon this subject than a text-book, which advocates scientific study of our knowledge of this important subject. Indeed, it is so much in the form of an essay that it does not seem particularly well suited for class work. On the other hand, the manner in which it has been compiled renders it a useful volume for collateral reading both in medical schools and in the advanced work of the ordinary literary institution. Some of the illustrations, as for example the one showing the typhoid bacillus and those of cholera and tetanus, are very indefinite and almost laughably minute, that on diphtheria, for example, being about a quarter of an inch square.

**AN ATLAS OF LEGAL MEDICINE.** By Dr. E. Von Hofman.  
Philadelphia: W. B. Saunders, 1898.

This German Atlas has been translated and edited by Dr. Frederick Petersen, of New York, and Dr. A. O. J. Kelly, of Philadelphia, and is a valuable contribution to the subject of which it treats. The medical reader of to-day is advantageously placed in that it is possible for publishers to provide illustrations of so true and natural a character as to make them of distinct value for medico-legal work. The illustrations, both

in black and white and in colors, are exceedingly good; only in a few instances do we find figures in which too much color is applied, as on Plate 45, where a stomach from a case of cyanide of potassium poisoning is illustrated. A very interesting illustration is Fig. 127, which shows a suicide perpetrated by a shot from a hunting rifle with a spreading ball. The spreading ball blew the head into an unrecognizable mass. There is no regular text in the volume, except that which serves to render the illustrations clear and useful—that is to say, each illustration is accompanied by complete descriptive text on the opposite page.

A SYSTEM OF MEDICINE. Edited by Thomas Clifford Allbutt, M.D. Volume VI.  
New York: The Macmillan Co., 1898.

As we pointed out in regard to the earlier volumes of this System, there is a pleasant impress of personality on the part of the editor throughout, and in his preface in the present volume, which is written as if he were writing a personal letter of explanation to each individual subscriber, we are told how it is that certain articles, notably that of Professor Welch, of Baltimore, have been unavoidably detained, and will therefore have to appear in the last volume of the System. This we presume will be numbered Volume VII, although it is referred to by Dr. Allbutt in his preface as Volume VI, although again the present volume is imprinted on its back and on its title page as Volume VI. It is only fair to state, however, that the inaccuracies and confusion which have existed in regard to the numbering of the volumes are the chief inaccuracies of the entire series.

The present volume deals entirely with diseases of the respiratory organs, namely, bronchitis, bronchiectasis, pneumonia, phthisis pulmonalis, pneumoconiosis, pulmonary aspergillosus, emphysema of the lungs, asthma and hay-fever, and syphilitic diseases of the lungs. We have turned with particular interest to the articles upon pneumonia and hay-fever. In the treatment of pneumonia the sensible statement is made that we cannot cut short the disease at the present time. After directions as to the necessity of keeping the bowels moving and the resort to ordinary hygienic procedures, we are told concerning special treatment that the temperature rarely needs the attention required by some other infectious diseases, and when it does require such attention the

cold sheet or Leiter's tubes may be used. The author, who is Dr. Pye-Smith, does not consider digitalis by any means as valuable in pneumonia as it is in the treatment of cardiac failure due to valvular disease. Bleeding is not to be neglected, nor is it to be overdone, and it is particularly indicated in those cases where there is distention of the right side of the heart and cervical veins. To our surprise we do not find any recommendation of the use of strychnine or atropine in the meeting of severe symptoms of circulatory or respiratory failure in this disease. Indeed, we think that beyond the points named the treatment outlined is distinctly unsatisfactory. In the article on hay-fever, a disease with which Englishmen are perhaps not so well acquainted as American practitioners, we are surprised to find that in the opinion of Dr. Goodhard a hypodermic injection of morphine stands first for the purpose of diminishing the violence of the dyspnea, and that pilocarpin is also a valuable drug where asthmatic attacks complicate the affection. He suggests the use during the attack of the inhalation of fumes from blotting-paper soaked in nitrate of potassium; in other words, he treats this condition much as he would an ordinary case of asthma. After reading the article on treatment of this disease we confess that we do not feel that we have gained much knowledge. These are, however, individual criticisms which in no way militate against the value of this volume. It is a System of which the Anglo-Saxon in America can be as proud as the Anglo-Saxon in Great Britain, and will prove of great use as a work of reference to medical teachers and practitioners on both sides of the Atlantic. We would not be without it.

HAY-FEVER AND ITS SUCCESSFUL TREATMENT. By W. C. Hollopeter, A.M., M.D.  
Philadelphia: P. Blakiston, Son & Co., 1898.

This little brochure of a little over one hundred pages of text represents to a large extent personal studies made by Dr. Hollopeter concerning this disease. He evidently writes almost entirely from the clinical aspect of personal experience, although at the close of the book there is a copious bibliography extending from 1565 to 1898.

After discussing the etiology and pathology of the affection he tells us, in the chapter devoted to treatment, that the daily sterilization of the nares and post-nasal spaces is a point of primary importance in hay-fever sufferers. The second point is to remove any abnormal

condition which renders the mucous surfaces hypersensitive. The local treatment consists in the use of the ordinary Dobell's solution sprayed thoroughly into each nostril, after which the mucous membrane is, to use Dr. Hollopeter's term, "scrubbed" by means of a piece of cotton on a cotton carrier, after which the mucous membrane is dried and a mild solution of menthol and albolene is sprayed in and the nostril is plugged for a moment in order to keep the oily application in contact with the mucous membrane. There is no doubt whatever that the antiseptic recommendations of Dr. Hollopeter are worthy of being universally followed.

CONSERVATIVE GYNECOLOGY AND ELECTRO-THERAPEUTICS. A Practical Treatise on the Diseases of Women and their Treatment by Electricity. Third Edition, Revised, Rewritten, and Greatly Enlarged. By G. Betton Massey, M.D. Illustrated. Philadelphia: The F. A. Davis Co., Publishers, 1898.

Although this volume professes to be a third edition of Dr. Massey's book upon Electricity and Diseases of Women it is in reality a new work, as the original volume has been so rewritten and increased in size that the two when put side by side do not show any relationship to one another save in the fact that both of them strongly urge the use of electricity in the treatment of a good many disorders which other gynecologists believe can only be remedied by distinct operative procedures. The book is divided into two parts, the first dealing with the modes of examining patients, studies concerning electricity, and the methods of its application to the diseases of the genito-urinary tract in the female in which electro-therapeutics are believed to be of value. The second part deals with the rudiments of medical electricity, and is devoted to an explanation of the physics of the subject and to distinct directions as to the apparatus to be employed. A noteworthy characteristic of the volume is the full-page illustrations which are to be found through it. A large number of these are from life and many of them are lithographs taken from paintings of living patients. In other instances they are actual photographs, in which can be recognized the author, one of his trained nurses, and the patient.

It is customary in most books of this character where an actual patient is photographed to so destroy the likeness as to make identification impossible, but a disregard for this custom which would do credit to a French novel is characteristic of some of these pic-

tures, as for example in Plate VIII or IX. However, *honi soit qui mal y pense*. It can be said on the other hand that these illustrations are unusually good, that they illustrate far better than many diagrams with which we are familiar the points to which electricity is to be applied for therapeutic purposes, and Dr. Massey deserves credit for the infinite pains which he has apparently taken to illustrate his subject. The question as to the usefulness of electricity in the genito-urinary affections of females we have no space to deal with. Dr. Massey is one of those who "out-Herods Herod," so to speak, in his confidence in these measures. There is no doubt at all that in a certain number of cases electro-therapeutics are exceedingly valuable in this class of patients. That fibroids and other large tumors can be removed by the use of electricity is, however, beyond our belief. The present volume nevertheless is so far as we know the best exposition of the subject in the English language. The early and comparatively imperfect editions which have preceded it have been unusually successful, and for these reasons the present volume cannot fail to prove popular.

A MANUAL OF OBSTETRICS. By A. F. A. King, M.D. Philadelphia and New York: Lea Brothers & Co., 1898.

This, the seventh, edition of Dr. King's small but very useful manual of obstetrics not only contains all that was good in the previous editions, but those facts which have been accumulated by the author in personal experience and from current medical literature since the last edition appeared. The success of this book has depended upon the fact, first, that it represented the teachings of a recognized authority; second, that the student and practitioner find the information that they desire in a concise and applicable form; and third, the size and price of the volume is such that it is within the reach of every one. The present edition will serve to still further increase the popularity of the work.

THE INTERNATIONAL MEDICAL ANNUAL FOR 1898. New York: E. B. Treat & Co. Bristol, England: Wright & Co.

This annual publication is now familiar to most practitioners in this country and abroad. The editor has called to his aid a number of men who are well known writers in the various branches of medicine, and they have abstracted from current medical literature most of the material which they consider

valuable. The present volume is equal to its predecessors in value. Like them it is copiously illustrated in black and white, and is also beautified by colored lithographs. The work deserves the success which has already been accorded to it.

## Correspondence.

### LONDON LETTER.

By RAYMOND CRAWFORD, M.A. OXON., M.D., M.R.C.P.  
LOND.

We have recently regaled you with details of the treatment of phthisis by large doses respectively of creosote and guaiacol, and now we would call your attention to the paper read by Dr. Russell, of Birmingham, at the meeting of the Midland Medical Society, on "Iodoform in the Treatment of Phthisis." Iodoform has recently in this country passed into complete disrepute as of any substantial value in the treatment of pulmonary tuberculosis, so that it is interesting to find some one who has a good word to say for it. After subtracting all cases in which the period of attendance was too brief, or other conditions too uncertain to build an argument upon, Dr. Russell minutely analyzes 123 cases. Most of the cases were treated with rapidly increasing doses of iodoform. The initial dose was usually two or three grains three times daily, and to this two grains were added weekly to each dose until a maximum dose of ten grains thrice daily was reached. In these cases the iodoform was habitually given along with cod-liver oil, but any fallacy arising from this cause has been eliminated by comparison with a group of cases treated with cod-liver oil, but without iodoform. The criteria of improvement that have been selected are alteration in physical signs, occurrence of hemoptysis, alteration in cough and night sweats, change in weight, and the subjective sensations of the patients themselves. Out of fifty-one cases available for investigation, as many as fifteen showed some improvement in the physical signs, and in five of these the improvement was marked—a very much larger proportion than in the cases treated without iodoform. The stage of disease in each series may be taken to all intents and purposes as the same. In fact, looked at from this point of view the iodoform treatment can hardly be said to have had a fair chance, as in out-patient practise the early and tractable cases tend

to discard treatment as soon as any improvement is felt, while only the advanced and hopeless cases persist to the bitter end. The statistics of hemoptysis under the treatment are quite valueless, as the series of contrast cases differ widely in the duration of the attendance, and *ceteris paribus* the longer the attendance the greater the likelihood of hemoptysis. Dr. Russell failed to find the same benefit for the night sweating that other observers have recorded from iodoform, and only a very slight influence on the severity of the cough. Every one will agree with Dr. Russell that there is no better index of improvement than gain of weight in phthisis, and in this particular the cases treated with iodoform show a marked advantage over the contrast series. We append the two tables for comparison:

#### IODOFORM CASES.

Attended 6 to 12 weeks.....	45
Gained, 19 { 1 to 5 lbs.....	15
{ 8 to 9 lbs.....	4
Lost, 19 { 1 to 5 lbs.....	12
{ 6 to 13 lbs.....	7
Stationary.....	7

#### CASES NOT TREATED WITH IODOFORM.

Attended 6 to 12 weeks.....	15
Gained, 5 { 1 to 5 lbs.....	4
{ 6 lbs.....	1
Lost, 8 { 1 to 5 lbs.....	6
{ 6 to 8 lbs.....	2
Stationary.....	2

A very large number of the patients expressed themselves as feeling decidedly better under the iodoform treatment. This cannot be attributed to the traditional optimism of phthisical patients, because, as Dr. Russell points out (and we have always maintained the same) the characteristic of phthisical out-patients at a hospital in a large town is profound and ineffaceable depression. From what we have said it will be seen that no great power for good is claimed for iodoform, but rather that it compares favorably with other drugs. In spite of the large doses employed in these cases, only two instances of toxic symptoms were noted, namely, two cases of temporary amblyopia.

The committee appointed by the Clinical Society of London at the commencement of the year 1895 to investigate the clinical value of the antitoxin of diphtheria have just issued their report. Their findings merely confirm the generally accepted belief in its efficacy not only to lessen mortality, but also to prolong the duration of life in fatal cases. Looking at the statistics of the cases of more or less marked laryngeal affection, the committee express themselves as very confident of the usefulness of antitoxin. In the first place,

nearly one-half of the cases of laryngeal affection escaped tracheotomy, while the mortality after tracheotomy was only 36 per cent. as against 71.6 in the series compiled from the statistics of general hospitals prior to the introduction of antitoxin. Translated into other terms, this represents a lessened tendency of the membrane to spread to the larynx and trachea, and a lessened danger in the cases in which such extension has occurred. The investigations also confirm the absence of any connection between the occurrence of paralysis and the amount of antitoxin injected. This is the more remarkable, as with a lessened mortality from the initial disease one would have expected an increase of the paralytic sequelæ. Joint pains beyond a doubt must be set down as one of the ill effects of the antitoxin, as they do not occur in the series not treated by antitoxin; and in nearly all the cases in which joint pains occurred there was also a rash and some rise of temperature. A rash occurred in nearly one-third of the 633 cases treated by antitoxin; the rashes were either erythematous or urticarial, but the former were much the more frequent. The date of eruption from the time of the first injection varied considerably, but in two-thirds of the cases it appeared between the sixth and the twelfth day, and the eighth day seemed to be the most favored day. In more than half the cases the temperature rose with the appearance of the rash, the duration of which was very variable. It will be seen that the report contributes little fresh material to existing knowledge, but it is of great value as the careful conclusion of a committee of conscientious clinical observers.

The special "Tuberculosis" number of the *Practitioner*, to which we called attention in our last letter, seems likely to bring about some practical assistance to the preventive treatment of tuberculosis in this country. Recently a meeting of many leading medical men was held at Sir William Broadbent's house to discuss measures for awakening the interest of the public. The first step has been taken in the formation of a society to disseminate knowledge as to the channels and modes by which tuberculosis is acquired, and should this preliminary effort meet with any adequate public response, it is proposed to establish sanatoria that shall be pecuniarily within the reach of all classes of the community. Dr. Burton Fanning has shown that the open-air treatment of phthisis can be successfully carried out even in the variable

and inclement conditions of climate that have fallen upon us in these latter days. He has tried it for a period of three years in a convalescent home at Cromer, details of which were published in *The Lancet* of last March. The whole of the twenty-two patients subjected to the régime benefited in some degree, and some to a remarkable degree. By means of shelters so constructed as to protect from rain, wind, and the glare of the sun, patients were able to spend as much as six and a half hours a day on an average in the open air; and it is probable that in an institution with a resident medical officer always at hand, even longer hours might have been allowed without risk.

Dr. Dreschfeld's paper to the Manchester Therapeutical Society on the therapeutics of diuretin is valuable. He had used it in acute Bright's disease, where the urine was scanty, and had found it increase the output of urine from 15 ounces to as much as 100 ounces in the twenty-four hours. The same good results were not obtained in post-scarlatinal nephritis. In chronic tubal nephritis he had sometimes found diuretin act when digitalis had failed, but the effects were as a rule transitory; while in interstitial nephritis he had found no benefit, and on the other hand a liability to excite toxic symptoms. Dr. Dreschfeld considers diuretin to be a powerful diuretic by virtue of its action on the epithelium of the convoluted tubules. He apparently does not believe in any primary action of the drug on the heart, but considers the relief to the heart secondary to the diuresis. This latter view we fancy is generally held, and has been confirmed by the experiments of Cohnstein on animals. In heart disease Dreschfeld found diuretin valuable in the treatment of mitral disease, especially when the symptoms had come on suddenly. In aortic disease—in which we have sometimes found it tolerated when digitalis was not—Dreschfeld found it of little use, and sometimes actually harmful; while in simple failure of the heart muscle without valvular lesion diuretin had sometimes done what digitalis had failed to do. In our own experience diuretin has always seemed a most capricious drug in the treatment of cardiac dropsy, sometimes acting like magic, at another time and in apparently identical conditions failing completely. It seems almost as though reaction to the drug were to some extent an idiosyncrasy. In cirrhosis of the liver Dreschfeld has got startling results from diuretin; he had seen as much as four or five

quarts of urine passed in the twenty-four hours. As with cardiac disease, the cirrhotic patients in whom the symptoms had come on suddenly were more amenable than the older patients in whom the onset was insidious. Foster, of New York, has stated definitely that it is useless for diminishing ascites in hepatic cirrhosis, but possibly all the cases in which he tried it may have belonged to the latter category. Dreschfeld found no benefit either in the dropsy of pericarditis or of peritonitis, but had employed it successfully in one or two cases of pleural effusion. The ill effects of diuretin, as with digitalis, seem to fall mainly on the digestive system and are evidenced in nausea and vomiting. Dreschfeld occasionally noted signs of collapse, a symptom quite in accordance with Cohnstein's experiments on animals. Dr. Dixon Mann suggests that some of the depressing effects of diuretin may be due to the salicylate of sodium it contains, and thinks that some soluble form of theobromine may be found more advantageous than diuretin. We should fancy that omission of the salicylate on the other hand would rob diuretin of one peculiar advantage it possesses in its marked action on the liver in addition to the other organs it affects.

Now and again we are confronted with alarming symptoms from an overdose of that very useful drug, exalgine. Such a case is reported in the *British Medical Journal* of June 11. In this instance the patient had taken an eight-grain dose. The account of the patient's sensations as given by herself and the very rapid recovery certainly suggest that hysteria lurked rather prominently in the background. We have ourselves repeatedly used four-grain doses two and three times a day and have never yet encountered any of the untoward symptoms for which we have always been on the watch. We do not, however, consider it a drug that can be satisfactorily given over a period of time, as its effects are transitory and usually very quickly induced; it will often cut short an attack of pain, and is thus a valuable ally to other analgesics of a slower and more persistent activity.

---

PARIS LETTER.

By A. R. TURNER, M.D. (PARIS).

In one of this year's numbers of the *Semaine Médicale* Dr. Maurice de Langenhagen, of Cannes and Plombières, published an article

on the affection known as muco-membranous enteritis. Dr. de Langenhagen's personal experience in treating this disease at Plombières, and the care he has taken to set out at length the treatment, make the article an interesting one.

The etiology and pathology were first considered. Regarding the former Dr. de Langenhagen is to be classed among those who think that the cause must be sought in an irritation of the cecum and colon, and perhaps of a portion of the small intestine, due to stagnation of the feces in the intestinal canal. This stagnation gives rise to an irritation of the mucous surface, affecting chiefly the glandular system, and consequently superficial only.

In almost every case the affection itself has been preceded by a period during which no other symptoms than obstinate constipation and at times the passage of membranes were to be noted. The constipation may date far back, to childhood even.

It is unfortunate that at this stage the patient too rarely calls the attention of the physician to his condition, and it may likewise be feared that in many cases the latter would not understand the importance of preventing the onset of an affection which is so painful both physically and mentally.

In one or two cases Dr. de Langenhagen has observed the seeming occurrence of the affection after an acute enteritis, and without a previous stage of long-continued constipation.

In treating muco-membranous enteritis three points should be considered, namely, the diet, the state of constipation, and the pain and discomfort suffered by the patient. However much it would seem rational to give a diet in which an abundance of cellulose and, generally speaking, coarse food would tend to prevent constipation, which is one of the chief symptoms, the very opposite is to be followed. The diet should in fact be as mild and concentrated as possible, and any additional constipation so produced must be met by the means spoken of later on.

Dr. de Langenhagen recommends in severe cases an exclusive diet of a mixture of eggs and powdered meat, until the improvement be such that a less restricted diet may be taken.

In acute attacks with dysenteriform symptoms milk may be used exclusively, but only for a short time, as it tends to increase the constipation.

I may say here that milk is disapproved of

by others who have had great experience in this affection, notably by Professor Potain of Paris, and by Dr. Baraduc of Châtelguyon, one of the two springs in France where most cases resort for treatment.

When the patient has recovered sufficiently to take a more generous and above all a more agreeable diet than eggs and powdered or raw meat, he may be given the following:

Thick soups made with arrowroot, rice-flour, barley-flour, oat-flour, or lactated food; eggs prepared in various ways; roasted or broiled meats, both dark and white, chopped up or cut into small pieces, and with the fat and gristle carefully removed; brains; sweet-breads; fish, such as sole or pike, but not oily fish, like salmon or mackerel. These fish may be boiled or fried in batter, but when eaten, the latter and the skin should not be taken. Lean ham not too salted is good.

Vegetables should be taken in small quantities only, and should be mashed; thus mashed potatoes or peas or lentils are good, but salads, string-beans, and I may add for the United States, green corn, are to be avoided.

It is undoubtedly better that such dishes should be prepared with as little butter as possible.

Fruit necessarily falls under the same interdiction as salads, especially when uncooked. A little cooked fruit, mashed and passed through a sieve, may be taken. No preserves are allowed.

Bread may be taken in small quantities only, and then stale, and it is better to replace it by some form of biscuit made expressly for dyspeptic patients. In some cases it is exceedingly difficult to induce the patient to give up bread, but its liability to ferment and its irritating action upon the intestine may render such action necessary.

For sweets, light dry cakes or custards or blanc mange are good. Pastry is to be avoided.

The patient should drink but little. Water is the best drink, though in some cases a mild beer mixed with water has been better supported. Weak hot tea taken at the end of the meal seems to have good effects in some cases. Wines and liquids containing alcohol should be most carefully avoided. Sauces, spices, game and fats may not be taken.

Even when recovery has taken place two articles of food must be forever laid aside, fat and alcohol. The latter seems to burn

the intestine of patients liable to muco-membranous enteritis. So much for the diet.

The constipation should be treated as follows: A good stool should be obtained daily. Castor oil is a favorite with many for this purpose. A teaspoonful in the morning is usually sufficient. It may be given in black coffee or mixed with some substance which will enable it to be taken with less trouble. In some cases, however, it seems to encounter a special abnormal susceptibility in the patients, who even after so small a dose as the above are really prostrated from the violent effect produced, and in whom the intestine remains for some days in a state of great irritation. In such cases small doses of olive oil, containing a few drops of castor oil, have been recommended by Dr. Malibran, of Mentone, who has practised at Plombières until recently.

Instead of the oily purgatives some physicians prefer small doses of sodium or magnesium sulphate, say from four to eight grammes every morning. Glénard of Lyons and Vichy recommends this treatment.

Podophyllin and belladonna, or cascara sagrada, with or without rhubarb and magnesia, may be given.

Dr. de Langenhagen does not look with favor on enemata used for the purpose of causing a movement of the bowels; he thinks that they soon dull the sensitiveness of the rectum.

Respecting local applications to the intestine, large enemata of hot water are useful, but should not be given too frequently. Borax (two grammes to the liter), sodium bicarbonate, or ichthyol (one to two tablespoonfuls to the litre) may be used. It is advisable to give these enemata by means of a reservoir raised from thirty to forty centimeters above the patient. The water should be boiled and allowed to cool to from 45° to 48° C. (113° to 118° F.). One liter may be introduced but not retained; following which from one-half to three-quarters of a liter should be injected and retained some minutes, during which the patient may be turned first on his left side, then on his back, and finally on his right side, in order to enable the liquid to penetrate as far as the cecum.

Pain and discomfort may be treated by the internal administration of tincture of cannabis indica or of belladonna. An excellent method is to cover the abdomen at night on going to bed with a compress wrung out of cold water, and covered over with flannel and oiled silk.

Local spasm of any particular part of the colon may be removed in a few minutes by means of massage executed with great gentleness over the region affected.

In France two mineral springs are recommended against muco-membranous enteritis. Plombières is considered by Dr. de Langenhagen to be more efficacious in acute spasmodic varieties of the affection. It is a pretty little village, situated in a deep and narrow valley of the Vosges Mountains near the German frontier. The valley is so narrow in one place that at its bottom there is room for but one street, in which when a carriage passes the passers-by are obliged to step into the door-ways and shops. Plombières was a favorite resort of the late Emperor Napoleon III. The spring is used chiefly in baths.

The second mineral spring, Châtelguyon, is in the center of France, and is considered by Dr. de Langenhagen as more especially suitable to torpid chronic forms of muco-membranous enteritis.

As I have just returned from a visit to Châtelguyon I will say a few words about the place itself.

In the very center of France, where lies Clermont-Ferrand, the capital of the department of the Puy-de-Dôme, is to be found a volcanic mountainous region. Here are situated several of the best known springs of France: Royat, at half an hour's walk to the west of Clermont-Ferrand; La Bourboule and the Mont-Dore, a few miles to the southwest; Vichy, to the northeast, on the other side of the fertile plain of the Limagne, which borders the River Allier, running north and south; and finally Châtelguyon, about fifteen miles north of Clermont-Ferrand. It is reached by a three-quarters-of-an-hour drive from Riom, a curious little town of about ten thousand inhabitants, one of the stations on the railway from Clermont-Ferrand to Paris.

Châtelguyon, though so near to Clermont-Ferrand, is not situated in the really mountainous region, but just on the edge of the latter. The village is built at the bottom and on the sides of a small round hill, once topped by a castle, and on which a Calvary has been erected. It is situated at a height of 360 meters above the sea. Its waters, which are given by between twenty and thirty springs, contain as their principal salts magnesium chloride and iron carbonate. Their temperature varies from 27° to 35° C. (81° to 95° F.), and they are charged with carbonic acid gas. Treatment is given by means

of baths and by the internal administration of the water. The springs give two million liters in twenty-four hours, and such is the quantity of water available that the baths may be taken, if desired, in the water running directly from the spring and escaping at once from the bath-tub. After a minute or two in the water the action of the carbonic acid gas upon the skin causes the latter to redden, while a slight burning sensation is felt.

Châtelguyon is recommended in muco-membranous enteritis, in all forms of constipation, in chronic appendicitis, and in dilatation of the stomach. Anemia complicated by constipation in young girls is treated with success. It has been found useful in enteritis and diarrhea due to the tropics. In brief, *atony of the digestive organs* is its chief indication.

The country to the back or west of Châtelguyon is wild and curious. The old Auvergne villages are picturesquely dirty, and the huddling together of the stone houses, cattle and men together in the same building, with narrow streets, is worth examining, and forms a striking contrast to the hôtel quarter of Châtelguyon.

In a walk I came across a man lightly ploughing with a wooden plough, tipped only with iron, and with but one long handle. Though not very old he told us that he could remember when it was the only variety of plough used in the country. Now it was used only to turn over ground already ploughed. Nothing is more common than to meet some old peasant woman watching a cow feed by the roadside, while under one arm she carries a staff around which hemp is bound, and with the hand of the other arm she twirls the spindle, spinning thread which some local hand-loom weaver will make into coarse hempen cloth for household use. In another part of Auvergne, or rather in what is called the Haut-Limousin, I have seen the women so spinning, but carrying the hemp on the broad brim of their head-dress, as they walked along, herding a cow or a pig or two or some geese.

This Haut-Limousin, which I visited some years ago, is not known to the tourist. It is a land of brooks and high mountains covered with gorse, where at the inn one may be served, as I once was, from a pear-tart measuring half a meter in diameter.

Dr. Schreiber, assistant at the Clinic of Internal Medicine at the University of Göttingen, has recently proposed the substitution

of sodium permanganate for potassium permanganate in cases of poisoning due to morphine or phosphorus. This he was led to do on account of the lesser toxicity of sodium permanganate.

A series of experiments on dogs convinced him that the effect of sodium permanganate was as efficacious as that of the potassium salt.

The following method of treatment is recommended by Dr. Schreiber: The stomach should be first washed out with 2:1000 solution of sodium permanganate, after which one-half liter of the solution should be swallowed or introduced by means of the tube, and retained.

When it is not possible to procure an apparatus for washing out the stomach, vomiting may be induced by a subcutaneous injection of apomorphine. This latter should, if possible, not be given by the mouth, in order to avoid counteracting the action of the sodium permanganate; in cases where the drug must thus be given, however, one-half liter of the sodium permanganate solution should be first administered, followed by a second half liter, when the vomiting has ceased.

Recent visitors to Paris must have noticed that the atmosphere, which used to be so clear, has become more and more smoky, owing to the increase in the number of factories and in some quarters to the smoke given off from the electric light works. It has accordingly been decided that all persons causing thick or prolonged smoke in Paris must within six months take means to do away with its production, under penalty of being dealt with as a public nuisance.

Dr. Deléarde, assistant professor at the Faculty of Medicine of Lille, has successfully treated five cases of painter's colic by means of subcutaneous injection of normal saline solution. The solution used was that recommended by Professor Hayem, of Paris; namely, sodium chloride 5 grammes, sodium sulphate 10 grammes, distilled and sterilized water one liter. In every case 500 cubic centimeters was injected, and in from 12 to 48 hours diarrhea lasting from two to three days appeared. The pains ceased after the injection and previous to the appearance of the diarrhea.

In all the cases treated in this way the subcutaneous injection of the solution seemed not to cause, as usual, a more abundant flow of urine, but to spend all its action upon the intestinal canal. The diarrhea due to the

treatment ceases in from two to three days without treatment. In every case the appetite was at once much improved.

#### BERLIN LETTER.

BY JAMES J. WALSH, M.D., PH.D.

The most interesting thing in therapeutics in Berlin during this past month was Koch's talk before the German Colonial Society on tropical malaria. In his experience of nearly two years in German East Africa, where malaria is very common, he found quinine an unfailing remedy for the disease; while a gramme ( $15\frac{1}{2}$  grains) a day was enough to completely protect the unacclimated against infection. He insisted that entirely too much quinine is administered in malarial regions and thinks that the dreaded "*schwarz wasser fieber*," malarial hematuria, is always, not a symptom of a pernicious form of malaria, but of quinine intoxication. He never saw it in a case where he could absolutely exclude the possibility of its being due to quinine, that is, never saw it in a patient who had not taken the drug; and as the idiosyncrasies for quinine are by no means rare, and when they exist often render the patient extremely susceptible, he has become thoroughly persuaded of the quinine origin of the hematuria.

Quite as surprising as this was his discussion of the possibility of the production of a serum immunity to the disease. There is here a question of an entirely different microbe to those that cause diphtheria or tetanus, an animal, not a vegetable, parasite, so that the master's declaration that the same laws as to the production of immunization probably apply here, as to the diseases caused by bacteria, is at least interesting. Koch has noted in the tropics that malaria in normally healthy individuals, even when entirely untreated, has a distinct tendency to be self-limited. The paroxysms of an attack become successively milder, and succeeding attacks have fewer paroxysms, and these are not so severe, until finally the individual acquires practical immunity, suffering but very slightly from malaria. Naturally, no one but those who have either had the disease themselves, or are protected by heredity, escape the disease. The inhabitants of portions of the tropics where the disease does not exist—and there are some such places in German East Africa—suffer as severely from the disease when exposed to it as Europeans,

though Koch has noted, and it is a tradition among the natives themselves, that after living in a malarial region for a while they do not suffer from the disease as before.

Koch looks forward then to the probability of artificial immunity protecting against the disease and so making possible the colonization of the rich tropical regions now forbidden to Europeans because of the disease. He considers the possibility of such immunity feasible even though we should know no more of the life history of the malarial parasite than we do at present, though he considers, too, that the theory of the mosquito being the intermediate host of the hematophagous of Laveran is a very probable one and that further research along this line will give us the life history of the parasite.

The treatment of other diseases where the microbic cause was unknown has become possible. The cattle plague for instance, to which Koch has devoted so much time during the last two years in South Africa without finding a definite bacteriological cause for it; whose microbium causus is possibly so small that his assistant, Dr. Kolbe, has just announced that it is probably beyond the power of the microscope as at present constructed to bring it into view, is no longer the dread destroyer that it was, since a protective serum has been found for it. The cause of hydrophobia has always remained a mystery, but the treatment for it and that too by biological means has been found. This is, I believe, Professor Koch's first public acknowledgement of the efficacy of the Pasteur treatment for hydrophobia.

The finding of an immunizing serum for malaria, even with our present defective knowledge of its cause, Koch does not consider impossible. The object is one eminently worthy of a patient investigator's time and labor, for it would confer untold benefit on mankind and open up rich but at present practically uninhabitable regions to colonization and civilization. The end to be attained he considers a much more important one than polar exploration, to which so much time is devoted by enthusiastic discoverers and so much money by governments.

At a recent meeting of the Berlin Medical Society Professor Silex, the ophthalmologist, treated the subject of atrophy of the optic nerve in tabes. In true tabetic atrophy he has never seen specific antisyphilitic treatment do good and he is sure that he has seen it do harm—that is, hasten the course of the disease when persisted in. A careful study of

some sixty cases has shown him that tabetic optic nerve atrophy is almost without exception post-syphilitic, and he agrees with Erbas to the etiological connection at least indirectly of syphilis with the disease, but must say a word of warning as to syphilitic remedies; especially is the *schmier kur* (the rubbing in of mercury into the skin—the usual specific treatment in Europe) liable to lead to rapid and complete loss of sight.

Professor Silex thinks that he has found that a mild continuous electric current applied to the temples produces good results. The progress of the disease is rendered slower, remissions occur oftener, and during the remissions distinct improvement of vision may be noted, as if the gentle electrical excitation of the unatrophied optic fibers led to a better fulfilment of their function and so sight was improved. Professors Oppenheim and Bernhardt agreed with him that the most satisfactory treatment was with the continuous current, and also as to the bad effects of mercurial treatment in these cases. Professor Oppenheim further dwelt on the symptomatic tabes which sometimes develops directly from syphilis and which is often so hard to differentiate. At times only the therapeutic test of the favorable reaction to antisyphilitic treatment absolutely assures the diagnosis. Yet the administration of specific remedies must not be begun unless there is something suspiciously atypical in the symptoms of a supposed tabes or in the course of the affection, and must not be continued longer than a couple of weeks, or irreparable injury will be done.

Professor Eulenberg discussed the treatment of neuralgia at a recent meeting of the Hufeland Medical Society, and there seems to be two things that the more exact diagnosis and observant therapeutics of the last few years have brought into prominence in the handling of this often so obstinate affection. First, so-called neuralgia is in a great many cases really not a local peripheral nerve affection, but a central affection, not a neuralgia, but a psychalgia, for which the only hope of treatment lies in the betterment of the general condition of the patient, with the expectation that the functional psychical trouble will grow correspondingly less. Hence the frequent benefit obtained from suggestive influences; against the abuse of which, however, Professor Eulenberg expressly warns and gives the striking example of a physician who, to relieve a constant neuralgic pain in

the neck, inserted an electrode into the esophagus and allowed several shocks to be given, with the deliberate purpose, so he told the patient, of killing the nerves that were giving the pain. He did stop the pain, but the patient now insisted that he was unable to swallow, the nerves of his esophagus having been killed; and the last condition was worse than the first.

The other resource in many cases of neuralgia that obstinately resist treatment is a long course of massage. The properly directed excitation of peripheral nerves when not carried to the extent of fatigue seems to exert a tonic influence upon the whole neuron or set of neurons affected.

A very interesting application of this principle of the tonic influence of peripheral nerve irritation is discussed by Dr. Lots in an article in the last number of Professor Leyden's *Zeitschrift für Klinische Medizin*. He uses especially two forms of mechanical cutaneous irritation. A rough sponge, or the spongy vegetable material known as Loofah, is used to produce, by gentle friction at first and then as the patient grows used to it by harder rubbing, for ten to twenty minutes at a time, a state of cutaneous hyperemia. Only a part of the body is uncovered and subjected to the process for the time being, so as to avoid chilling. His second method is walking barefooted over pebbles, *i.e.*, little rounded stones about one centimeter ( $\frac{1}{8}$  inch) in diameter. This last is an excellent local remedy for cold feet and consequent sleeplessness, and is said to be rather pleasant than otherwise for the patients. These two sets of cutaneous irritation are claimed to give excellent results in habitual headache, and in the relief of that tired feeling and other general symptoms that accompany neurasthenic conditions.

In its inventor's hands the method has also been successful in the treatment of that depressing condition for the physician, the ailing state that so often develops in precocious children, who have been allowed and encouraged to do serious mental work when too young, and in whom there is seen want of appetite, restless sleep, vivid dreams, talking in their sleep, and night terrors. Cutaneous irritation has also proven of service in palpitation of the heart where it was evidently of nervous origin. Doubtless the effect of the method is mainly its suggestive influence, but anything that will do good in these unsatisfactory conditions cannot but be welcome to the practitioner.

## REPORT OF AN ANOMALOUS CASE OF MORPHINE POISONING.

To the Editor of the THERAPEUTIC GAZETTE.

SIR: A. C. L., aged forty, had been suffering from a lacerated wound of foot for two weeks. The wound at this time was in good condition, but somewhat painful. He was called for breakfast on the morning of June 12 and appeared well, but declined to eat anything. About 8.30 A.M. he was heard, by some one in the next room, breathing heavily, and at 9.30 he was found apparently dying, and we were summoned. Dr. E. E. Horn, of this place, was also called. On arriving at 10 A.M. we found him lying on his back, mouth wide open, absolutely comatose. Pulse 70, full and regular. Respiration typically Cheyne-Stokes, and stertorous, about 15 per minute. The skin was cool and moist, cyanosed and mottled over chest and abdomen. The hands, feet and legs were cold. The throat, trachea and larger bronchi were filled with mucus, producing coarse, bubbling râles. The pupils were pin-point in character, equally contracted. No paralysis of any part of body was found; the muscles were completely relaxed. About one pint of urine was drawn, which was a little darker than normal in color.

A diagnosis of opium poisoning was at once made, and partly confirmed by finding about eighty grains of morphine in his pocket. One-fiftieth grain of atropine,  $\frac{1}{8}$  grain strychnine nitrate, and  $\frac{1}{8}$  grain nitroglycerin were given hypodermically, and hot bottles placed about patient. Very little change was noticed after this.

At 10.30 A.M.,  $\frac{1}{8}$  grain atropine and  $\frac{1}{8}$  grain strychnine was administered. The pupils dilated to 3 m.m.; the respirations became more regular with less stertor, and less mucus was present in throat. The pulse was 90; the feet and hands warm, and cyanosis less marked. At noon five grains of potassium permanganate and one ounce of whiskey were given, but no change occurred. At 2 P.M. the pulse was 110 and somewhat irregular; after one-tenth grain strychnine nitrate was given it again became regular. At 4 P.M. we gave  $\frac{1}{8}$  grain strychnine and  $\frac{1}{8}$  grain atropine. The pulse was now 130, the respirations 30. At 5 P.M. the pulse was 150, weak and irregular. His breathing was becoming more shallow, and the mucus was increasing in throat. The skin was more cyanosed. We gave tincture of digitalis, 22 minims. At 5.45 P.M. death occurred with a single spasm of flexors of arm.

The heart beat one minute after respiration ceased. Artificial respiration was kept up thirty minutes after this with no signs of returning life. After the extremities became warm they remained so till some hours after death. Thirty-six hours after death the whole of right side and the external genitals became enormously distended with gas and much discolored. As all injections were made into the right side, and especially into the gluteal region, the question arises whether this had anything to do with the production of the gas.

No attempt was made to evacuate the stomach either by the use of emetics or the stomach tube, firstly, because the morphine had been taken on an empty stomach and was probably all absorbed by this time; secondly, because of the deep coma, the spasmodic character of the breathing, and the large amount of mucus in the throat, in our opinion the use of either would have been attended with great danger of sudden death from asphyxia.

At no time could the patient swallow; hence no antidotes could be used except those which could be administered hypodermically.

Our diagnosis was based on:

1. The bilateral equal contraction of the pupils.
2. The deep coma and clammy skin with cold extremities.
3. The fact that a large quantity of morphine (two drachms) had been purchased three days before by the patient, who was not addicted to the morphine habit, and a diminished quantity (80 grains) was found upon his person when seen by us.
4. The fact that large doses of atropine failed to produce any marked mydriasis.
5. The absence of any paralysis which with the equally contracted pupils would exclude cerebral hemorrhage or embolism.
6. The negative condition of urine with history of patient, which obviates the possibility of its having been uremic coma.

Some of the remarkable features of this case are:

1. The peculiar character of the breathing, at no time less than 15 per minute, increasing to 30 half an hour before death, and at first typically Cheyne-Stokes. From the literature now accessible we are unable to find any instance of Cheyne-Stokes breathing in opium poisoning.
2. The temporary dilatation of pupils after the administration of atropine, followed by

their contraction, although the use of atropine was continued.

3. The great heat at surface of body continuing till long after death. (We regret not having taken the temperature.)

4. The early appearance of coma so profound that patient could not be aroused by any means.

5. The distention of right side only, after death. Injury of foot was on left side.

Our time was occupied so completely by our practise that we did not do a post-mortem, and as the coroner did not consider it necessary under the circumstances, none was done.

Yours truly,

DRS. BRADFORD & COLCORD.

AUSTIN, PA.

#### *CASES OF INTUSSUSCEPTION.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: I read with considerable interest your article on intussusception in the June number of the THERAPEUTIC GAZETTE, and regret that I did not know of your interest in this subject, as I could have added two very interesting cases to your table of this extremely rare affection. My first case occurred in 1888, and as I was then a young practitioner, having graduated from the University of Pennsylvania in 1885, and realizing the gravity of the affection, I did not assume to manage the case without assistance and therefore called in consultation one of Trenton's most prominent physicians, Dr. Joseph Bodine, now deceased, who verified my diagnosis of intestinal intussusception.

The patient was a girl aged seven years, with a history of obstinate constipation. The symptoms were typical—sudden onset of pain, constipation, tumor in left iliac region, muco-sanguineous stools, vomiting, and subsequently great abdominal distention. The treatment was medical; no effort was made to replace the bowel. In about eight days after the onset of the trouble the child was seized with most intense abdominal pain, followed in about a half hour by a free evacuation of the bowels. The stool contained a mass of sloughing intestine about three inches in length. The convalescence was protracted. There was for some time pain and tenderness on pressure over the abdomen, with alternating constipation and diarrhea, the stools containing a considerable quantity of mucus tinged with blood. Eventually, however, she entirely recovered, apparently without

stricture of the intestine. She is now a strong and vigorous girl, and singular as it may appear, since the attack the bowels have been regular.

My second case I had quite recently. On May 5, 1898, I was requested by Dr. James Cooper, of Trenton, to see with him a case of intestinal obstruction in a boy aged five years, with history of obstinate constipation since birth. On April 30, while playing on the floor, he suddenly complained of severe pain in his abdomen; during the night he had a small fecal movement. From that time until I saw him the symptoms were typical. Tenesmus, vomiting, bloody stools and constipation were present. Upon examination I found the abdomen greatly distended and extremely sensitive, so that I could not make out the tumor. His pulse was 128, small and compressible, respiration 40, and temperature 99°. He had fecal vomiting at frequent intervals. I did not unnecessarily distress the child by examining through the rectum, although had I done so I am sure from the position of the tumor I should have been able to feel it. My diagnosis, based entirely upon the history, was that of intussusception, and I informed the family that the child would within a few hours die; but at their urgent request and with a clear understanding that the boy would in all probability die under the operation, I consented to open the abdomen. I had the child removed at once to Mercer Hospital, Trenton, and within an hour opened the abdomen, and found low down in the pelvis on the left side, close to the sigmoid, a portion of small intestine invaginated for about five inches; near the constriction were numerous ulcerated spots and beginning gangrene. The bowel was firmly adherent and could not be drawn back. Above the constriction the intestines were intensely red and greatly distended. At this stage of the operation the child began to sink rapidly, and without further effort to repair the bowel the abdomen was closed. In about fifteen minutes the child died. After death I removed the specimen.

Very truly yours,

JOSEPH B. SHAW.

TRENTON, N. J.

#### *APOCYNUM CANNABINUM AGAIN.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: Referring to the alleged utility of *Apocynum Cannabinum* in dropsy, I beg to say that I have used the drug in the form

of fluid extract in three patients, two of whom were suffering from cardiac dropsy and the third with hepatic dropsy. In neither case did it do any good, but, alas, in one resulted in dangerous cardiac poisoning, and for eight hours I was not sure that the patient (a woman of twenty-eight years) would live a half-hour. A medical friend of mine used the drug in two cases, but without any benefit accruing therefrom.

In a medical journal I see a Cincinnati physician reports its use in a case of dropsy with edema of the feet. He reduced the dropsy, he says, but about that time the patient died from "nose-bleed." His case reminds me of the Irishman who determined to teach his horse to live without food. He complained afterwards that about the time when the "baist" was trained to live without "ateing," it died.

Yours truly,

M. C. JENNINGS, M.D.

CHICAGO, ILL.

To the Editor of the THERAPEUTIC GAZETTE.

SIR: I have before me your current issue and have noted Dr. Dabney's claim to the discovery of Apocynum, and that his use of the drug and his article on the subject runneth back to a period of "nearly twenty years ago." I have before me, also, a copy of "The American Eclectic Dispensary," published by John King, M.D., of Cincinnati, and dated 1855, which says, speaking of Apocynum: "As a hydragogue cathartic, and also as a diuretic, in those instances where this effect is displayed, it has been found most useful in dropsy." Apocynum has for more than half a century, while yet Dr. Dabney was in his swaddling accessories, been a strong item in the treatment of "dropsy" by eclectic practitioners. Personally I am a regular practitioner, but I like to see the proper hat hung on the right peg.

Yours truly,

HENRY M. COWEN, M.D.

MT. STERLING, ILL.

#### *THE ADDRESS IN OBSTETRICS.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: In the Address in Obstetrics, June number, page 386, the printer has used the word "peritoneum." Obviously it should be "perineum," as it was written in the MS.

Very truly,

A. S. TOWLER.

### THE PATHOLOGY AND TREATMENT OF CHRONIC VARICOSE ULCERS OF THE LEG.\*

BY ERNEST LAPLACE, M.D., LL.D.,  
Professor of Surgery and Clinical Surgery in the Medical-Chirurgical College; Surgeon to the Philadelphia and St. Agnes's Hospitals.

Chronic varicose ulcers of the leg form a class of cases which not only haunt the hospital wards, but are a burden and lasting reproach to the surgeon. Only those who have

dealt with a great number of these cases can realize the amount of careful treatment they demand in order to reach any degree of improvement, and only these can realize the disappointment and discouragement that follow a return of the trouble soon after the improvement. In order, therefore, to apply the rational treatment to these rebellious sores, we must first consider their pathology.

The varicose ulcer is appropriately named such because it depends for its existence upon a serious disturbance of the superficial circulation of the leg. This disturbance results from the dilated and weakened condition of the veins, producing a certain amount of stasis, distending the skin, causing an

\*Read before the Pennsylvania State Medical Association, Lancaster, May 18, 1898.

edema, which requires a very little traumatism to produce an excoriation, which is the starting-point of the ulcer. If we inquire as to the initial cause of varicose veins we are confronted with a very obscure problem in pathology, and can only say that the walls of these veins are weakened by a process of malnutrition, resulting from an impaired condition of the whole system. The veins are weakened most probably in the muscular coat; the column of blood which they are intended to support excites a stronger pressure within their caliber than they are able to withstand, and as a result dilatation ensues. This dilatation renders the valves of the various veins almost useless in supporting the column of blood, and the veins acquire at times an enormous distention. An erect posture, and especially such vocations as require constant standing, tend to aggravate the pathological conditions just described, and as a result, from the time a slight traumatism or excoriation has removed the epithelium from the passively congested limb, an ulcer exists whose tendency is, by the impairment of the circulation, to grow constantly larger, and to be accompanied by venous hemorrhages.

The effort at repair on the part of Nature immediately results in the formation of granulations and cicatrization. On the other hand infection sets in, and suppuration complicates the case. In the acute stage these ulcers are soft and tender, and rather hemorrhagic, but after having existed for months or years the chronic irritation of the edges of the ulcer and the neighboring parts results in the formation of fibers within the surrounding cellular tissue, whereby a hard callous condition ensues. This hardening further impairs the circulation, so that in time the varicose ulcers possess a dull pink, glazed appearance, showing a great lack of blood about the parts. This scarcity of blood is due to the compression of the neighboring parts by the chronic inflammation which accompanies the ulcer.

For years, in hospital and private practise, I have given special attention to the treatment of these ulcers. The chief dependency has been the application of the modern principles of asepsis, combined with rest. Having treated the patient so as to improve his general condition, I proceeded under ether to remove freely the edges of the ulcer and scrape its surface, transforming the ulcer into a healthy wound. The patient was then kept at rest in a recumbent position so long

as was required to entirely heal the ulcer. The wound was dressed at proper intervals so as to maintain it constantly in an aseptic condition. In a majority of instances, by dint of great efforts, I succeeded in healing the ulcer. The patient would be advised to wear an elastic stocking, and to keep off his feet as much as possible. It was impossible in many cases to follow this advice, inasmuch as most of the patients belonged to the laboring class. As a result, from use of the limb, I often found that the place where the ulcer was soon became congested, blue, and swollen, reproducing the same old ulceration. It is in these cases that both patient and surgeon feel so discouraged.

Analyzing these unfortunate cases, I find that the treatment of the ulcer was based on the proper principles. I removed the cause of the ulcer by placing the patient in bed, eliminating the passive congestion which accompanies the varicose vein. The ulcer was healed by removing the infectious element and transforming it into a healthy aseptic surface, whereon Nature was enabled to build fibrous tissue and cover it up with epithelial cells. So far everything was correct and the indications of treatment were properly fulfilled. But from the time that the patient was allowed to walk again, and the same original cause was again at work, it was natural that the effect should also be the same, and show itself in the return of the ulcer. The weak point in the treatment, therefore, was the fact that the varicose veins and their effects were not permanently eliminated. I believe that the removal of the cause—that is, the cure of the varicose veins—should be the initial step for the successful treatment of these ulcers, and therefore advise that all the veins of the leg be ligated and obliterated as the first step in the treatment. The treatment of varicose ulcers of the leg, acute or chronic, to-day should resolve itself into a radical cure of varicose veins of the leg, and as a result the ulcer will immediately take on a tendency to heal, and will require only ordinary attention to help the healing process. Furthermore, the cause being removed in the complete obliteration of all the superficial veins, the ulcers once healed remain permanently so, allowing the patients to attend to their work with impunity.

For the obliteration of the veins I have performed one of two different operations according to the nature of the varicose veins. In some instances the superficial veins of the

leg are persistently dilated, but the long and short saphenous veins are not distended. In this case a catgut ligature is applied to these veins as they enter respectively the saphenous and popliteal veins. This method was advised by myself in the year 1892, and has met with success in this class of cases. Inasmuch as these two veins drain the whole of the venous circulation, their ligature results in a simultaneous stasis and coagulation of blood within all these superficial veins. Their obliteration soon follows.

On the other hand, when other great masses of enlarged veins form on the limb, and do not affect the saphenous vein above the knee, I practise Schede's method, which consists in making a circular cut, about two inches below the knee and directly through the skin, separating all the veins as they present themselves, clamping them, and subsequently ligating them with catgut. The circular cut is then carefully sutured. This is the most effective method of stopping the superficial venous circulation and obliterating the veins, which hampered the process of healing.

These wounds, after the obliteration of the veins, heal most kindly when thoroughly aseptic, and from the first the operation exerts a beneficial effect upon the ulcers. They immediately acquire a more healthy appearance, and granulations set in which effectually build tissue, while the surrounding epithelium grows and covers the ulcer, completing the healing process.

The combination of an operation for the obliteration of the venous circulation and the proper local treatment of the ulcer according to modern surgical methods fulfil all the indications in this rebellious class of cases. Since I have adopted this method I have obtained very flattering results in the most obstinate, old and callous ulcers at the Philadelphia, Medico-Chirurgical and St. Agnes's hospitals during the last three years. A series of eighteen ulcers of the worst varieties healed and remained so. A detailed description of the cases would be rather tedious, since the principles involved in each one are precisely the same, and only require such modification as the peculiar location and character of the sore may demand.

I believe that syphilis and tuberculosis may complicate at times these varicose ulcers, hence we should never lose sight of the diathesis under which the patient may suffer, so as to eliminate it by the proper treatment before the surgical aspect of the case is undertaken. In syphilitic ulcers accompanied by

varicose veins we have given a general mixed specific treatment in addition to a local application of a salve consisting of ammoniated chloride of mercury five grains to one ounce of vaselin.

When the sore had taken on a healthy appearance, and the tissue seemed comparatively free from specific poison, the operation upon the varicose veins was undertaken—not before. In tuberculous ulcers, complicated by varicose veins, a general tonic treatment was given consisting of the syrup of hypophosphites and a local application of iodoform powder. I always take care, however, to first remove all diseased tissue by the curette, and paring the edges of the sore. When the healing process, after the wound had become healthy in character, seemed slow, threatening to take a long time before the epithelium would spread over the edges and cover the surface, skin-grafting was practised, according to Thiersch's method. The granulating surface was thereby covered thoroughly with epithelium, and in the course of two or three weeks would be completely healed.

This process of skin-grafting consists in removing large strips of epithelium from the thigh in the following way: Having rendered the strip aseptic it is made tense by being supported between the thumb and the middle finger of the left hand; using an ordinary razor or sharp knife, the instrument put at an angle of  $20^{\circ}$  to the thigh and practising a see-saw motion, the epithelium is, if possible, removed without penetrating below the papillary layer of the skin. These strips of epithelium may measure one-fourth to one-half inch in width, and three, four or five inches in length, according to the necessities of the case. Aseptic gauze is applied to the spot whence the epithelium was removed and secured by a bandage; this will suffice as treatment for this excoriated surface. The spots of epithelium are made to cover the ulcer completely, and are secured in position by several thicknesses of sterilized gauze smoothly laid over the parts.

Should suppuration, however, set in, and the life of the grafts be in danger, this danger is overcome by the various layers of the gauze having been made detachable, so that when the dressing is removed all the layers of gauze can be taken away except the lowermost layer. In this way the growths are not disturbed. The secretion and pus can be removed effectually through this lowermost layer of gauze.

Peroxide of hydrogen will clean the wound thoroughly through this one layer of gauze, and the application of any antiseptic solution is made possible without disturbing this last layer. In this case it becomes necessary to repeat our antiseptic washing at least every day. At the end of a week or ten days it will be found that all of the grafts have adhered, whereas, should all the dressings have been removed when there was evidence of suppuration, usually on the third or fourth day, these grafts would have been sacrificed.

I believe this to be a very practical point, essential to success in a great number of cases. From experience I have found that it is not always possible to devote our best endeavors to maintaining an aseptic condition of the ulcers, especially if they have been grafted. A light bandage applied to the limb for a short while before the patient is allowed to get up suffices to complete the treatment of what has for a long time been a very distressing condition, both for the patient and for the surgeon.

---

THE VALUE OF DIPHTHERITIC ANTITOXIN IN THE TREATMENT OF MEMBRANOUS CROUP.

---

By L. I. MATTHEWS, M.D.,  
Joplin, Missouri.

---

In the preparation of this paper I have not thought it necessary to lengthen it by discussing the nature and cause of diphtheria or the propriety of using antitoxin in its treatment. If the value of any new remedy has been almost universally acknowledged by the profession, it is antitoxin in the treatment of diphtheria. The reduction of the death-rate in this disease after its employment has been so marked that one can hardly find a physician of standing who will question the propriety of its use. What may be said of its use in general in this disease may be also said in regard to its employment in laryngeal diphtheria. In those cases where the membrane extends from the pharynx to the nares and larynx, its value is unquestioned. This class of cases, a large majority of which under the use of the old remedies we expected to see die, we now treat with a reasonable expectation of success. All now regard antitoxin as the remedy *par excellence*.

So much as a prelude to the value of the use of antitoxin in a class of cases generally designated as membranous croup.

I do not care to provoke a discussion upon

the identity or duality of membranous croup and diphtheria. I believe that so far as the histological characteristic of the exudate is concerned, no difference is found. I also am willing to concede that in about eighty-five per cent. of cases of membranous croup examined, the Klebs-Loeffler bacillus is present. Pathologically it would seem that membranous croup is simply diphtheria locally manifested in the larynx. When we come to the clinical side of the subject, how is it? I know that in practise in a large city, where one very seldom sees a case of croup without an exudate in the pharynx and all the depressing symptoms found in diphtheria, one will be persuaded that there is only this clinical difference, namely, there is added to the signs of an exudate in the pharynx the other distressing symptoms due to stenosis of the larynx because of pseudo-membrane deposited on its mucous surface. Unfortunately for the children, membranous croup is found in localities other than those densely populated and where diphtheria is endemic. In the country, in smaller cities, towns and villages pseudo-membranous croup prevails, and its clinical characteristics are wholly unlike diphtheria, except only the symptoms which one would naturally expect—laryngeal obstruction. All these cases are attended with a frightful mortality.

The fact is that prior to the introduction of antitoxin in the treatment of this disease, the physician who was called to one of these cases, fully developed, expected it to die. I saw my first case in 1878. Since then I do not think a year has passed without either my seeing one or more cases of my own or seeing one in consultation. Prior to this last year I never saw but one well developed case get well, and that was in a boy thirteen years of age. Perhaps others situated as I have been may have been more fortunate, but this has been my experience.

Now what is the clinical picture of the cases I have treated? and I believe they are the same as those of other physicians who have been situated as I have been. First, as a rule, the children attacked are strong and healthy, excluding those cases which occur following measles and scarlet fever. The first thing noticed is slight hoarseness, which gradually increases. There is some elevation of temperature, with increased heart's action. The child, however, feels reasonably well, and in the very large majority of cases is allowed to be up and around or even play

out-of-doors. In nearly all of these cases an examination of the throat will reveal no exudate. The hoarseness and fever gradually increase, and before very long slight laryngeal obstruction is observed, followed by complete suppression of the voice. After a greater or less length of time this obstruction becomes marked. The inspiration is prolonged and becomes labored; the muscles of thorax and abdomen are called into increased action; there is precordial and intercostal depression on inspiration. Cyanosis supervenes, and unless relief is had the child dies from exhaustion, the result of its labored effort to get air and from carbonic acid poisoning. There are no symptoms of depression or septic infection so characteristic of diphtheria. The child dies from strangulation and not from systemic infection.

These cases are, almost without an exception, sporadic; they are not infectious. I have never known of two cases occurring in the same family, nor have I ever witnessed anything in this connection which would indicate a possibility of the disease spreading from one family to another. If the disease is diphtheria, it is so mild, so far as its specific character is concerned, as to be unable to propagate itself, or to produce those constitutional symptoms which are so marked in genuine diphtheria.

I have never witnessed a case where there was glandular involvement, nor have I ever heard of a case which after recovering was followed by paralysis or any other nervous sequelæ. The exciting cause of an attack I believe is due to an exposure to sudden changes of the weather, and especially when the prevailing wind is cold and from the northeast and east. These cases are not observed during an epidemic of diphtheria. My observation is that as a rule the croup was manifest at periods of time when there was nothing to indicate that this disease was in any way connected with other cases of diphtheritic disease in the near or remote surroundings; and while I try to quarantine my patient, it is only for the reason that authorities whom I do not care to disregard advise this, and not because I believe the disease is infectious or contagious.

From what I have written it will doubtless be seen that while I do not deny that, from an etiological and pathological standpoint, membranous croup and diphtheria may be one and the same disease, yet clinically they are as different as two diseases can be—that is, different so far as the important symptoms

are concerned. Of course, the symptoms of laryngeal stenosis in membranous croup and laryngeal diphtheria are common to both.

Taking into consideration, then, this clinical difference in croup and diphtheria, and not being fully convinced of the identity of the two diseases, is it to be thought strange that one would commence the use of antitoxin for the relief of membranous croup with but very little confidence in the virtue of the remedy? I think not. Without having full confidence in the propriety of using antitoxin in laryngeal diphtheria, it required a measure of actual trial and experience with this remedy to give me any faith in its use in membranous croup. I have used it, and although a skeptic at the commencement, still I administered it with the determination to give it as fair a test as though I had unbounded confidence in its remedial virtues. I gave it in fairly large doses; I relied upon it to the exclusion of all other remedies, with the exception of stimulants, and in eleven cases had only two deaths. The following is a list of cases and results:

CASE I.—Boy, aged seven years. Two doses antitoxin; recovery.

CASE II.—Boy, aged three years. One dose antitoxin; recovery.

CASE III.—Girl, aged five years. Three doses antitoxin; recovery.

CASE IV.—Boy, aged two years. Three doses antitoxin; recovery.

CASE V.—Boy, aged four years. Two doses antitoxin; died.

CASE VI.—Girl, aged two years. One dose antitoxin; died.

CASE VII.—Girl, aged two years. Two doses antitoxin; recovery.

CASE VIII.—Boy, aged four years. Two doses antitoxin; recovery.

CASE IX.—Girl, aged two years. Two doses antitoxin; recovery.

CASE X.—Girl, aged three years. Two doses antitoxin; recovery.

CASE XI.—Girl, aged two years. Two doses antitoxin; recovery.

The first case was seen October 31, 1897; the last case April 15, 1898. These eleven cases occurred in the practise of my partner, Dr. Yates, and myself (except two, which I saw in consultation). These two had been given the usual remedies without benefit, and only commenced to improve after the administration of the antitoxin. My experience in these cases is somewhat different from what I had been led to expect from those who advocate the use of antitoxin in this class of

cases, viz., that relief did not come speedily. In the first case improvement was seen in twelve hours; in none of the others under twenty-four hours; in some, not until forty-eight hours had elapsed. When improvement came it was marked, the respiration becoming easy in a very few hours. The remedy in connection with the stimulants seemed in a remarkable degree to sustain the little sufferers in their labored efforts to breathe. In the eleven cases the antitoxin was administered twenty-three times; not a single unfavorable symptom was observed, except in one case, in which an eruption appeared after the second dose. In all the others no reaction, no rash, no depressing symptoms of any kind, and no local inflammation or abscess at point of injection. In none were the kidneys affected.

It will be logically argued that this report, if it means anything, is a strong argument in the support of the doctrine of the identity of croup and diphtheria; perhaps—but I do not believe any one will advocate the doctrine—that puerperal fever and erysipelas are one and the same disease, notwithstanding the fact that the antistreptococcic serum is of great value in both diseases and is held to be curative in these cases. One cannot be too emphatic in advising the early use of the remedy, antitoxin, in membranous croup. The sooner it is administered, without doubt the greater prospect of success. Another point, which I think should not be lost sight of: give large doses to begin with, and an increase if favorable symptoms are not observed. Use from 1000 to 1500 units, and repeat in the same or larger-sized doses every twelve hours if necessary. As soon as obstruction is marked and breathing labored, give stimulants in full doses in connection with the antitoxin.

In eight of the eleven cases Parke, Davis & Co.'s antitoxin was used. Its purity and uniform strength cannot be questioned, and the neat and thoroughly aseptic method of placing it in the containers, ready for the physician's use, makes it, I think, above all others the most desirable preparation.

---

*THE CONSERVATIVE TREATMENT OF  
FIBROID TUMORS OF THE UTERUS.*

BY E. E. MONTGOMERY, M.D.,

Professor of Gynecology in the Jefferson Medical College of Philadelphia.

The influence of fibroid growths of the uterus upon the general health of the patient is dependent to a large degree upon

the situation of the tumor. Thus an intramural, or mural, tumor of small size which encroaches upon the mucous membrane will early give rise to profound disturbance of the menstrual function and consequently upon the nutrition, while an extramural growth will remain without symptoms and only be discovered by accident. As the first class produces symptoms, it will necessarily compel consideration of the best method for combating its baneful effects, but those growths which develop beneath the peritoneum and are only recognized by accident may seriously lead to question as to the wisdom of their being subjected to any interference.

Considering all uterine fibroids, it becomes then a question, first, as to what may be considered proper reasons for subjecting them to treatment, and second, what shall be the course of interference. Among the indications which will be so apparent as to require no discussion is the occurrence of hemorrhage at the regular period, but excessive in quantity, causing the length of the period to be greatly prolonged; or intermenstrual irregular bleeding, induced by exposure, fatigue, excitement, or the sexual relation. In either class of cases the patient may become profoundly anemic and a lowered state of vitality result, which will be favorable to the development of intercurrent diseases.

Instead of hemorrhage the patient may suffer from a profuse, enervating mucus, or muco-purulent discharge. Small growths may cause agonizing pain, uterine contractions similar to those of parturition. This symptom characterizes the intra-uterine fibroid, which the organ regards as a foreign body, and upon the expulsion of which all the energy of the uterus becomes concentrated. The pain may be so great as to demand the use of morphine for its relief, thus endangering the formation of a pernicious habit. Pressure upon the pelvic veins may produce edema of the lower extremities, of the vulva, and even of the tumor itself. Symptoms of peritonitis may develop trouble with the bladder, the rectum, or one or both ureters. Such diseased conditions are most frequently produced by pressure. I have repeatedly seen pressure upon the ureters result in their dilatation and that of the pelvis of the kidney until the latter organ was sacculated, with the greater portion of its structure destroyed. Large growths will disturb the respiration. Fatty changes are likely to occur in the heart. Necrosis may occur in the

structure of the tumor, with the formation of pus, thus greatly increasing the danger either with or without operation. Degenerative processes of a malignant character are possible. Sarcomatous infiltration of the tumor is the most frequent form. With mural fibroids I have twice seen the mucous membrane of the entire uterine cavity undergoing epitheliomatous change. The influence upon pregnancy is not without interest. Occasionally a fibroid will disappear under the changes of pregnancy and the subsequent puerperium. Not infrequently the patient will abort; sometimes the tumor, as the result of the increased tissue change in the uterus, will so rapidly enlarge that interference becomes necessary to relieve the oppression. Where the patient reaches the full term of pregnancy her danger is by no means past. The tumor may be so situated as to prove an obstacle to the progress of labor, or the involvement of the uterine wall cause irregular and ineffectual contractions, thus greatly delaying delivery.

The bruising of the tumor capsule during labor sets up inflammation, favors infection and subsequent suppuration. The processes of involution may arrest the nutrition in the growth and lead to loss of vitality and necrosis. Patients advanced in years are often advised that the menopause will arrest the growth and even lead to a decrease in its size, with relief from all of its annoying symptoms, but experience demonstrates that this cannot always be assured. In the mural and intramural varieties, the climacteric is generally delayed, pain and hemorrhage are increased. Even subsequent to the menopause abnormal changes are not precluded.

A deposit of calcareous material can take place in the tumor wall, and the circulation be so involved that necrosis results. The advent of the menopause does not always mean arrest of growth, for these tumors frequently increase in size. This enlargement is, however, more frequently produced by edema than from actual tissue growth.

Medical treatment affords but little encouragement. It is ineffective to control hemorrhage, and while it aids in securing the extrusion of the growth and thus renders it more accessible to surgical procedure, it is exceedingly tedious and not without danger from necrosis through the too marked interference with nutrition.

The various alterative and absorbent remedies have not produced results worthy of consideration.

The disappearance of such tumors under

the employment of electricity has been so rare as to justify doubt in the correctness of the diagnosis and observation. Generally, electricity does afford relief by diminution of the blood-pressure in the uterine wall, reduction of the inflammation in the connective tissue enveloping the growth, diminution or cessation of the pain, and the disappearance of the hemorrhage; but these beneficent results are not always secured.

Various other methods of local treatment, such as dilatation of the neck, section of the enveloping mucous membrane, massage of the uterus and tumor mass, hot douches, intra-uterine injections of solutions of iron or iodine, curettement, castration and ligation of uterine arteries, are neither always effectual nor free from danger. I saw one patient have a severe pulmonary congestion and edema following an intra-uterine injection for the control of hemorrhage induced by a submucous fibroid. The same patient later became insane. Curettement may be followed by suppurative in the tumor or its capsule, and cause death from sepsis. Ligation of the uterine arteries, while attended with some danger of sepsis, still leaves the growths, which must undergo a process of retrogression not unattended by possible peril. Aside from the limited number of cases in which a pedunculated fibroid could be removed through the vagina, until within a few years no other opportunity was afforded the patient suffering from growths in other portions of the uterus for their removal than through a sacrificial operation involving the uterus, tubes, and ovaries.

While not claiming to present an original device or method of procedure, it is my purpose to maintain that there are many uteri from which a sessile, submucous, an interstitial fibroid or multiple growths can be removed by enucleation, leaving a healthy functioning organ. This practise under proper aseptic precautions is attended with less shock and discomfort to the patient than the apparently more simple operation of extirpation of the organ. Whether the growth shall be attacked through the vagina or by way of abdominal incision will depend upon its situation, size, and the previous condition of the patient. Pedunculated or sessile, submucous and interstitial growths which have not attained too large a size to pass through the pelvis should be attacked through the vagina, unless the patient is unmarried and the vaginal orifice undilated.

When the growth is so large as to rest

above the brim of the pelvis, the uterus occupied by multiple growths, possibly comprising every variety, or the vagina small, the abdominal route is preferable.

Necessarily, not every patient will present conditions favorable for such an operation. The uterine structure may be so extensively involved as to preclude its successful retention, or be complicated by disease of the appendages so severe as to render restoration of function impossible. In such cases a sacrificial operation must be done. The ideal operation is one which removes the disease and leaves an organ capable of performing its normal functions. This operation may be done more frequently than it has been practised in the past. It consists in an enucleation through a minimum incision, using for this purpose a blunt dissector as occupying less space and affording less danger of carrying infection to the injured tissues.

The operation is done either by the vagina or through an abdominal incision. In the majority of cases the abdominal incision would be required. Small growths more or less pedunculated, which have partially or completely dilated the cervix, produce but little difficulty in either diagnosis or treatment. Where the cervix is not sufficiently dilated to afford investigation and exit for the growth, a bilateral incision can be made and the tumor rendered more accessible. Where the tumor is situated within the cavity of the uterus, with a cervix which is more or less long and undilated, the difficulty is more marked. An investigation of the situation and the size of the growth with its relation to the uterine wall is an important prerequisite to an operative procedure. To secure such an investigation is necessary that the canal should be dilated in order to permit the introduction of the finger. This dilatation may be accomplished by repeated gauze packing (Vulliet), dilatation with bougies (Hegar), the use of tents, or bilateral incision of the cervix to or beyond the internal os (Péan). Bilateral incision would seem too radical a measure for a mere diagnostic purpose, and with proper dilatation will be unnecessary for the removal of some growths. The situation of the incision would be impracticable, or embarrassing, in the treatment of others. Vulliet's method is slow and not always effective. The use of bougies will cause the cervix to be badly torn before the canal is sufficiently opened to admit the finger. Dilatation by tents is the most satisfactory. Sponge tents are the most effective,

but are so difficult to render aseptic and so easily infected that their employment is not advisable. The hollow laminaria tent of good size will in the great majority of cases render digital exploration possible within twelve hours. Where the canal is insufficiently dilated with the first tent, it may be carefully cleansed and the dilatation accomplished by a second relay of tents. If the surgeon is unprepared for operation at the time of the digital exploration, this dilatation may be maintained twenty-four hours longer by gauze packing. Rigid asepsis must be the rule in all these procedures. After the tumor has become accessible to the touch, further procedure must depend upon its situation, size, and relation. A small pedunculated tumor will in this manner be almost as accessible to manipulation as if it were situated in the cervix.

Recently I treated an unmarried woman, thirty-five years of age, who had suffered for over a year with irregular menstruation. The periods, which had formerly lasted from one to three days, now continued from ten days to two weeks. She had frequent severe cramp-like pains during the period. The uterus was but slightly enlarged. Near its fundus could be recognized a hard mass which was slightly movable. Two laminaria tents were introduced on the 14th of January, 1898. Upon their removal the following morning the finger could be introduced to the fundus and a fibroid polypus was discovered. A tenaculum was passed on the finger and caught in the pedicle. The tumor, steadied by this, was hooked by a second, with which it was delivered, the small pedicle breaking. Subsequent careful exploration disclosed this to have been the only growth. The fibroid was the size of a small hickory-nut. Convalescence was undisturbed.

In 1885 I saw an unmarried woman, forty-five years of age, who was so exsanguinated by repeated hemorrhage that the condition had been pronounced malignant disease. Dilatation with laminaria tents revealed a sessile fibroid the size of an egg situated in the posterior wall, which was delivered by enucleation after bilateral incision of the cervix. The cervical wound was sutured. The patient recovered after a prolonged convalescence due to faulty technique.

In September, 1896, a young married woman came under my observation, who had begun to suffer from dysmenorrhea and menorrhagia after a fall from a hammock.

Her health was broken and the condition aggravated by a valve lesion, causing mitral regurgitation. Owing to her constitutional condition, efforts were made by the use of ergot, and subsequently thyroid extract, to relieve the condition without operation, but the treatment was attended with such unpleasant results that it was discontinued. The fundus of the uterus was considerably enlarged. Dilatation revealed an interstitial fibroid the size of an egg in the posterior uterine wall. An incision was made from the uterine cavity through the intervening wall with the hope that the administration of ergot would facilitate its extrusion, but the drug was so injurious and she became so much depressed that I decided, regardless of her constitutional condition, to resort to radical operation. Under chloroform the uterus was dilated with bougies. A bilateral incision was made through the cervix, the tumor exposed, seized with a double tenaculum, and enucleated. The cavity was thoroughly irrigated and packed with gauze, the end of which was brought out at the os. The canal was restored by lateral sutures. Convalescence was uninterrupted.

In larger growths occupying the anterior wall a bilateral incision is unsatisfactory. The growth may be rendered more accessible by a circular incision through the vagina in front of the cervix, and splitting the uterovesical septum. Then a vertical incision through the anterior lip and wall of the uterus will expose the growth, which can be enucleated. If it is large, its delivery can be expedited by morcellation. Where necessary, one need not hesitate to incise the peritoneal cavity, but where the growth is situated well above the cervix the incision need not extend through the latter, but be made transverse and vertical; in other words, a T incision with the stem upwards, in this way exposing the growth and enucleating it. After the growth has been removed, the uterine incision should be closed with continuous catgut suture, and the peritoneum and vagina reattached to the uterus. Occasionally an incision through the posterior lip will render the growth more accessible, and if necessary Douglas' pouch may be cut into, the tumor or fundus of the uterus turned down, the growth enucleated, the wall sutured, the uterus replaced, and the wound closed.

The abdominal route affords easy access to large and multiple fibroid growths. After opening the abdomen the uterus is raised up, walled off from the abdomen by gauze pads,

and the incision made over the growth where it is most accessible, the mass seized with a double tenaculum, and the enucleation completed with a blunt dissector. Bleeding vessels may be secured by hemostasis. All growths, however small, should be removed. That the growth is submucous or intra-uterine need be no bar to its removal through the abdominal incision. Where possible the growths should be removed through one incision.

Alexander reports twenty-six tumors thus removed; but the uterine structure should not be torn up unnecessarily in order to bring all the growths through a single incision, as frequently less mutilation will occur by making two or three incisions. Previous curettement and insertion of gauze drain where it is probable the uterine cavity will be opened has been advised, but such advice is unwise, because the gauze packing may result in embarrassment in determining it from a growth, and still more if it is necessary to invade the uterine cavity. All incisions should be closed with continuous catgut suture in double rows. Where the incision is deep, the last includes a good portion of the peritoneum. In one patient I removed thirteen fibroids, five of which were intra-uterine; in another nine, the largest of which was the size of a child's head. In one operation I split through the fundus of the uterus into its cavity, extending the incision some distance upon the anterior wall. The surface was resutured and the patient recovered without abnormal symptoms. The largest tumor (weighing two and one-half pounds) thus removed was in a woman thirty years of age married, in whom the growth had come on up the cervix and had dilated the os so that the finger could reach the tumor. As the vagina was undilated its removal through that canal was not feasible. An abdominal incision was made, the uterus raised, and an incision made through its posterior wall. Then with blunt dissector the small uterus was peeled off the very large tumor, leaving quite a large cavity, which was closed by buried and superficial catgut sutures, a gauze drain having been passed into the vagina through the cervix. The woman, with the exception of an elevation of temperature to 103° on the third day, did well. This temperature soon subsided, and her convalescence was subsequently uninterrupted. She had been completely exsanguinated, prior to the operation, by the repeated hemorrhages. The great advantage

of this plan of treatment is that it leaves the patient free from mutilation, and even though she should not subsequently become pregnant the hope has not been removed, and the patient is spared the unpleasant phenomena incident to a premature change of life.

Of course it is important in the consideration of any plan of treatment to consider its mortality and subsequent effect on the health of the individual. Engstrom recently reported one hundred enucleation operations with four deaths. In my own experience the shock and constitutional symptoms have been much less marked in these operations than in those of hysterectomy. Another important consideration is the subsequent effect upon the uterus; thus it has been objected to this operation that there may be small growths in the wall of the uterus which are unobserved and may subsequently develop. This has not been the experience, however, in the hands of Martin and others, who have practised this method extensively. Another consideration is the influence upon subsequent pregnancy. In Engstrom's one hundred cases four became pregnant. The difficulty in basing any statistics upon this, of course, can be readily understood, when we take into consideration that of the one hundred and thirteen cases reported by Martin, forty-six per cent. were unmarried, and twenty-seven per cent. were over forty years of age.

Of the four cases reported by Engstrom which became pregnant, one aborted during an attack of typhus at the fifth month, again became pregnant, and aborted at the third month. She had been married seven years previous to the removal of the growth, and was never pregnant. The second had been married and yet without pregnancy. Ten intramural myomas were enucleated, from the size of a hazelnut to that of a hen's egg, besides a pedunculated fibroid the size of a duck's egg. This patient aborted at the fourth month. The third had a tumor the size of a hen's egg enucleated from the anterior wall. Pregnancy followed and reached full term, and she was delivered without difficulty. The fourth case had had three abortions prior to the operation. Intestinal adhesions to the left ovary and fundus uteri were separated in the operation, the left ovary extirpated, and a myoma the size of a walnut enucleated from the depth of the anterior body wall. Eight months subsequently the patient conceived, and at the time of the report was three months pregnant.

Olhausen cites three cases of pregnancy following enucleation.

This operation, then, has the advantage, as we have already noted, that it does not preclude the possibility of pregnancy; that it saves the woman from the psychic symptoms resulting from the sacrifice of important organs; that it is not attended with any more danger than, if as much as, would result from the extirpation of the uterus with the growths.

#### POISONOUS HONEY.

---

BY RALPH STOCKMAN, M.D.,

Professor of Therapeutics in Glasgow University, Glasgow.

---

In the THERAPEUTIC GAZETTE of February Dr. Voorhees describes a case of poisoning by honey; and again in the issue of May Mr. Edmund Jenner refers to the same subject and instances the well known case of the Greek troops as described by Xenophon in the Anabasis. Mr. Jenner states that the poison is derived from either the *Nerium Oleander* or the *Datura Stramonium*. The origin of the poison is, however, now well known, as exact researches have been made on this curious subject. It is probable that bees may obtain poison from various plants, but there is now no question as to the special plant which furnished the honey, the effects of which have been so graphically described by Xenophon.

Poisonous honey is still well known in the neighborhood of Trebizond, on the shores of the Black Sea, and in 1887 Mr. E. M. Holmes, of London, obtained a quantity from the British Consul. It was handed over to Dr. J. C. Thresh and myself for investigation, and Dr. Thresh has published a very interesting account of poisonous honeys (*Pharmaceutical Journal and Transactions*, 1887-88, vol. xviii, p. 397), including specially the Trebizond variety. We obtained the active principle of the honey nearly pure, and it gave characteristic chemical reactions, showing that it is identical with andromeda-toxin, the poisonous constituent of *Rhododendron ponticum* (*Azalea pontica*), and numerous other plants of the order Ericaceæ (Plugge, *Archiv der Pharmacie*, 1889). Experiments which I made on animals with the substance extracted from Trebizond honey showed that it had a stupefying effect from paralysis of the brain and spinal cord, the respiration being especially affected, while the heart remained comparatively untouched. Death occurs from paralysis of the respiratory center.

Later Plugge (*Archiv der Pharmacie*, vol. xxix, 1891) made an interesting contribution to the subject, in the course of which he states that it is a matter of popular knowledge in the neighborhood of Trebizond that the poisonous honey is derived by the bees from the flowers of *Rhododendron ponticum*. Plugge, however, settled the matter in another fashion. By means of fine capillary tubes he sucked up the saccharine matter from the flowers of *R. ponticum*, and experimented with it on animals. These experiments gave the characteristic effects of Trebizond honey and of andromedatoxin.

Any one who is interested in the question will find much relevant information regarding poisonous honey in the paper by Dr. Thresh, cited above.

---

*EUCAINE HYDROCHLORATE "B" AS A  
LOCAL ANESTHETIC IN THE NOSE.*

---

BY LEWIS S. SOMERS, M.D.,  
Philadelphia, Pa.

---

In the THERAPEUTIC GAZETTE for January, 1897, I reported a series of cases of hypertrophic rhinitis in which eucaine was used as a local anesthetic, to obviate the pain consequent upon cauterization of the turbinal tissue. In many ways this drug was found to be unsatisfactory as compared with cocaine, especially as to its lack of ability to shrink the engorged cavernous tissue. Since that time eucaine "B" has appeared, and its use in a series of cases, as a local anesthetic in the nasal cavity, forms the basis of this communication.

The drug is a white, crystalline powder, of neutral reaction, and sparingly soluble in water at ordinary temperature, but the solubility is increased by the addition of heat, and in the latter instance precipitation occurs in a short time as the temperature of the solution falls to that of the surrounding atmosphere; this may be overcome, however, by repeatedly warming the solution as desired, the addition of the small amount of heat necessary to raise the temperature being sufficient to clear the solution, not interfering in any way with its anesthetic powers. It is non-irritating and possesses but a small degree of toxic property as compared with cocaine or the previously mentioned form of eucaine, and being closely allied to both these drugs and also to tropacocaine, it partakes in a degree of their general properties. It differs from the other local anesthetics

mentioned, inasmuch as its ability to produce anesthesia is not impaired by boiling, thus allowing of perfect sterilization. It is also supposed to possess a "slight antibacterial action," but this has not been proven and is of little or no value. To properly prepare the solution it is advisable to use sterile water without the addition of an antiseptic, and heat the mixture until solution is effected, when it is ready for use. Wishing to compare this form of eucaine with cocaine as generally used for intranasal anesthesia, it was desired to make a four per-cent. solution, this being the same strength of the latter drug; but preparing it in the same way with water at 75° F., it was found that all the drug would not dissolve and it became necessary to make a three-per-cent. solution, the water taking up a sufficient amount to make a clear solution of this strength.

The cases studied were in both sexes and the ages varied, the youngest being nine while the eldest was thirty-two years. In all cases there was hypertrophy of the turbinal tissues, the inferior generally being selected for cauterization, and chromic acid fused on a probe was used as the cauterant. A three-per-cent. eucaine solution was applied to the parts desired by means of a cotton plug saturated with the drug, but all excess of fluid was pressed out. The plug was then placed in the nostril over the tissue to be cauterized, and as no data was available to determine the time required to produce complete anesthesia, it was allowed to remain *in situ* for eleven minutes in the first case; then the time was reduced by one minute in each subsequent case, until it was found that complete anesthesia reached its maximum in eight minutes after the application of the solution. In less time than this some pain was usually felt when the cauterant was applied, but if allowed to remain for eight minutes anesthesia was as complete as when a four-per-cent. cocaine solution was used, showing that eucaine is as efficient in this respect as cocaine in stronger solutions. The duration of anesthesia is considerably shorter than when cocaine is used, first reaching a maximum in the time previously mentioned, then rapidly diminishing in intensity, so that within a few minutes after the anesthesia becomes complete its effects are dissipated, the time required for the local action of the drug to disappear being about fifteen minutes. This refers to fresh solutions, but after the drug commences to precipitate, which is about the third day after

being freshly prepared, the precipitate increasing in quantity every day after this, the anesthetic properties progressively diminish, but the solution is still useful, its value remaining unimpaired for three weeks; and after this time it is of little value until the end of the fourth week, when it no longer acts as an anesthetic.

In all cases except three no effect was produced on the mucous membrane, it remaining unchanged under the influence of the drug, while in the three cases one gave evidence of a slight degree of congestion very probably due to traumatism from too much pressure in inserting the cotton plug; and in the other two cases shrinking of the membrane was observed in but very moderate amount. No untoward local effects, such as an excessive amount of irritation, were noticed, and what is still more important, there were no constitutional evidences of the action of the drug. Used in the amount necessary to anesthetize the nasal mucous membrane for minor operative procedures, it was found to exert only its local action, and possessed no untoward action at all on the other tissues of the body. It was observed that the unpleasant taste and partial loss of sensation in the pharynx when cocaine is used in the nasal chambers were entirely absent except in one case; this was but trifling, however, and was the consequence of using an excess of the solution to see if this more or less unpleasant action would take place. That it did not occur in all the other cases is probably due to the slow action of eucaine as compared with cocaine, and not to a smaller amount of solution, for the same quantity was used, it being desirable to have all the conditions similar, so that the comparison could be as accurate as possible.

From a study of the results obtained by the use of eucaine "B," the following conclusions as to its value compared with cocaine and the former eucaine may be deduced:

1. Eucaine hydrochlorate "B" in three-per-cent. solution produces as complete anesthesia of the nasal mucous membrane as does a four-per-cent. solution of cocaine.

2. Its action is slower than the latter drug.

3. The anesthesia is dissipated more rapidly than that produced by cocaine.

4. It is non-toxic in the strength and manner here used.

5. As it has no apparent shrinking action on the turbinal investiture as has cocaine, it is therefore less valuable for nasal surgery than the last mentioned drug.

6. It is superior to the former variety of eucaine because its toxic properties are less, it is more rapid in action, is non-irritating, and the same degree of anesthesia may be produced by smaller amounts of the drug.

#### GLANDULAR THERAPY.

VOGT in the *Revue de Thérapeutique* of May 15, 1898, is reported as having given a summary of the actual state of glandular therapy before the French Congress of Internal Medicine in April of this year. He states that medication by means of testicular juice is generally abandoned, but medication by means of ovarian juice is gaining in favor. The ovary is employed in dry powder or in tablets, or in a glycerin extract. Sometimes patients are intolerant to it, but usually two to four grains a day are given. It is employed in the following diverse conditions: To overcome the results of double ovariectomy, to combat the troubles of the menopause, to overcome sexual atony, to combat chlorosis. It is useful, too, in osteomalacia and for nervous maladies, such as hysteria, neurasthenia, and exophthalmic goitre. Extracts of the cerebral and medullary substances are practically abandoned, save the use of the pituitary body in the treatment of acromegaly. It is stated that practically no good results have followed the use of bone-marrow in pernicious anemia or chlorosis, nor has extract of spleen done good in malarial poisoning.

Brunet has reported a case of chronic bronchitis treated with pulmonary juice, with diminution in the expectoration. Extract of kidney has been used to treat anuria and to overcome uremic poisoning and dyspnea. It is claimed by Gilbert that it decreases albuminuria and modifies the severity of the disease. The suprarenal glands have been used with asserted advantage in asthenia as well as in Addison's disease, but the use of the pancreas for diabetes is still in the experimental stage.

In regard to the value of the liver, it is stated that in a case of cirrhosis with delirium the daily ingestion of three ounces of fresh liver causes the rapid disappearance of cerebral trouble, and that it has been used in the case of severe alcoholic cirrhosis with advantage, the hemorrhage being stopped, the delirium ceasing, and the color returning. In diabetes the results from its use are variable.

### THE PHYSIOLOGICAL ACTION OF HIGH ALTITUDES.

The time has passed when pure empiricism dominated therapeutic procedures. At first we began by learning more and more of the physiological action of drugs and so became more successful in their application to pathological processes, and side by side with these advances others have been made in studying the physiological effects of remedial measures other than drugs.

Our attention has been forcibly called to this matter by a paper which has recently been published by Dr. Solly, of Colorado Springs, embodying his remarks made before the Philadelphia County Medical Society upon the "Blood Changes Induced by Altitude." It has been known for many years to medical men that the most powerful means of cure at our disposal in many diseases consisted in sending the patient to a climate which would exercise a favorable influence over his malady. At one time sea voyages of a prolonged character, or residence for many months upon islands situated far off from the mainland, which provided

patients with a pure ocean climate, were the favorite resorts of consumptives, but increasing knowledge has shown us that while the fresh air and sunshine of these regions is distinctly advantageous in the majority of cases of pulmonary tuberculosis, high altitudes give better results. It was thought at one time that the physiological effects of high altitude, both upon the well and diseased, depended upon the diminished amount of oxygen present in the air, but more recently it has been discovered beyond all doubt that these symptoms arise because of diminished oxygen tension, there being at high altitudes a condition in which the molecules of air are more widely separated than at the sea level. It is also a well known fact that after a person has been at an altitude for a considerable period of time he can take more and more exercise with less and less discomfort, and that instead of the altitude making him ill he is very apt to develop a degree of healthfulness in excess of that which he possessed when at a sea level. This is due to the fact that the system produces blood changes as a result of which a greater quantity of oxygen can be absorbed, this change consisting in an increase in the number and size of the red cells and in the proportion of hemoglobin which they contain. Thus, as pointed out by Solly, the ordinary number of red cells, varying from 4,000,000 to 5,000,000 in a healthy adult, may be raised to 8,000,000 by residence at a high altitude of say 15,000 feet; that at Colorado Springs, which has an altitude of 6,000 feet, it may be raised to 6,000,000. In other words, the increase in the blood of a healthy resident of the Atlantic coast after a few weeks' stay at Colorado Springs would be about sixteen per cent.

It is evident, therefore, that in addition to the beneficial influences of pure air, intense sunlight, increased respiratory activity and exercise there are definite hematic changes which are even more beneficial to the invalid. It has been claimed by some that the greater blood count of persons living in a high altitude is merely a relative increase due to dryness of the air, which causes less liquid in the blood; but on the face of it this claim is absurd. The specific gravity of the blood is unchanged by altitude, and the increase which we have spoken of is not simply relative, but actual. Solly also points out that residence at a high altitude produces a normal hypertrophy of the cardiac muscle, and what is still more curious,

that both animals and man after they are acclimated can endure longer and run faster than they could when living at a lower level. Thus he cites the fact that bicycle racing at Denver has shown records which support this statement, and that race horses also make good time. The fact is also pointed out that the altitude produces a reduction of blood-pressure with a relaxation of the vessels, and that as a result the peripheral capillaries are constantly filled with blood, which accounts for the ruddy hue of those persons who live for any length of time at such an altitude as we have named, while the cool air and hot sun act as antagonistic stimulants upon the surface of the body and indirectly upon the nervous system.

One of the most important portions of Dr. Solly's paper is the emphasis which he lays upon the necessity of prescribing a definite climate for a definite case. As he expresses it, "an altitude is a bad climate for an invalid fool," and we might add altitude is a bad prescription for the physician to give his patient without due consideration of the physiological effects of the region and of the individual characteristics of his patient. Briefly expressed, it may be stated that exceedingly nervous patients as a rule do not do well at a high altitude, as it is apt to increase their insomnia and nervous irritation. In addition to this, it is a fact that in most high altitudes the conditions are unfavorable to persons suffering from genito-urinary diseases, and that persons suffering from fatty degenerations of the various organs, and particularly of the heart, do not receive benefit in these regions, but on the contrary may be injured. Finally, it should be remembered that a climate cannot regenerate organs which have been destroyed by disease any more than can drugs, and patients so far advanced in pulmonary tuberculosis as to be necessarily hopeless cases should not be made to spend their energies, their funds and their store of hopefulness in a vain search for the El Dorado of Youth which is as far beyond their reach as was that of the early Spanish seekers after it in pre-colonial days.

#### THE THERAPEUTIC VALUE OF METHYLENE BLUE.

---

A valuable summary of the physiological and therapeutic activities of methylene blue has recently been contributed to the *Revue de Thérapeutique Médico-Chirurgicale* of April 1,

1898, by d'Aulnay. In his concluding contribution upon this subject he gives an interesting and exhaustive list of the diseases in which this remedy has been employed internally, with mention of the names of the clinicians who have employed it, and follows this by another list in which he details in a similar manner its external applications. As he well points out, methylene blue possesses three properties: First, it is a coloring agent; second, it acts as a microbicide or disinfectant; third, it possesses distinct analgesic properties. It is with its microbicide influence that we first became familiar with the drug, and most physicians are familiar with the papers of Stilling in which he described its powers in destroying micro-organisms and urged its use as a local antiseptic. But its value as a pain reliever is even more noteworthy. Combemale believes that its analgesic properties are in part due to the transformation of oxyhemoglobin into methemoglobin, but we cannot understand how this is possible. Amongst the diseases in which it may be employed with a certain advantage internally we find cancer of the stomach, malaria, nephritis, hypergastric acidity, and as an antineuralgic for facial or sciatic pain. It is also said to be useful in rheumatic pains, and has even been given in ataxia and angina pectoris and migraine, with asserted success. A considerable disadvantage in its use is, of course, the manner in which it stains everything with which it comes in contact, and when taken by the mouth it stains the mucous membrane and gives a disagreeable styptic taste. For this reason it is better to give it in pill or in cachet. Absorbed by the stomach and intestine, it colors the capillaries through which it passes and stains the lymphatics—indeed, all the tissues with which it comes in contact are stained by it, except the peripheral nerves.

---

#### POISONING WITH BISMUTH.

---

Many years ago it was the custom of teachers of materia medica to point out that bismuth was capable of producing poisoning with gastro-intestinal inflammation; later it was found that this substance never produced such symptoms unless it was contaminated by arsenic; and finally, it remained for Villemin and others to point out that it was capable of producing chronic poisoning with the formation of black sloughs in the mucous membrane of the mouth and

gastro-intestinal tract, desquamative nephritis and albuminuria. Still more recently in the *Centralblatt für Innere Medizin* for March 5, 1898, there are abstracts of two cases in which poisoning followed its use. In one of these more than an ounce of a ten-per-cent. solution of aïrol with equal parts of glycerin and olive oil was introduced into a cold abscess after it had been evacuated. Three days later the patient had severe stomatitis and the buccal mucous membrane was black in color. Although the emulsion was withdrawn from the abscess cavity, this blackening of the mucous membrane persisted for two weeks. In the other case, a man took fifteen to thirty grains of bismuth subnitrate, and shortly after an eruption developed, resembling that of scarlet fever. This lasted four or five days, and the skin then came away in shreds resembling desquamation, this being particularly noticeable upon the hands and feet.

The second case does not appear to us to be definitely one of bismuth poisoning. It would seem to us to be rather one of the dermatites, occurring by coincidence, perhaps, as a result of the locking up in the bowel by the action of the bismuth of some toxic material. Perhaps it was a case of dermatitis exfoliativa, which in its mild form is sometimes called erythema scarlatiniform.

#### FOREIGN BODIES IN THE BRONCHI.

---

This important subject has recently been dealt with in an interesting manner by Dr. Lendon, of Adelaide, South Australia, in the *Intercolonial Medical Journal*. He was led to study the literature of the subject by the occurrence of a case in his own practise, the case itself being of very considerable interest.

A boy of seven years drew into his bronchus an ebonite shirt stud, was immediately seized with asphyxiation, and was in great distress for a number of hours. For three days subsequently he felt pain in the chest at a spot corresponding to the second right costal articulation. During the succeeding year he suffered from constant cough and an attack of acute pneumonia which commenced with moderate hemoptysis, and finally with a purulent and offensive expectoration. At the end of the year it was also noticed that no air was entering the upper part of the right lung, and fourteen months after the accident he came under Dr. Lendon's care. There was great dyspnea, constant coughing,

profuse fetid expectoration, as much as half a pint being brought up in twenty-four hours. There was also marked evidence of hectic fever. Under these circumstances surgical interference was decided upon, and an incision was made into the chest, one inch of the fourth rib being excised. The pleural cavity was emptied, but puncturing the lung did not show any collection of pus. On breaking up some slight adhesions between the middle and right upper lobe a small quantity of pus was liberated, and while manipulating the lung the operator believed that he felt the stud, but immediately afterward lost it.

After the patient recovered from the anesthetic, during a violent fit of coughing the stud was expectorated. This was followed for a few days by great dyspnea and a rapid pulse, but ultimately the boy recovered and has now been in good health for several years.

Lendon goes on to a consideration of the physical signs of a foreign body in a bronchus and finds that they consist in complete obstruction to the entrance of air on the side which is suspected, dulness on percussion, and on auscultation loss of vocal fremitus and resonance, although if the obstruction be partial air may enter the lung, be retained, and produce some resonance. After the acute irritation due to the presence of a foreign body passes by, there is a quiescent stage followed by one of definite inflammation of the bronchus, lung, or pleura, due to the entrance of a foreign body, and under these circumstances septic pneumonia and hematemesis may develop. When an organic substance is swallowed capable of undergoing decomposition and becoming putrid, we not only have these symptoms but those of septic infection, and an abscess of the lung may form. In conclusion Lendon thinks there is rarely any difficulty in deciding which side of the chest is affected.

In regard to the prognosis he points out that a foreign body may remain in the bronchus for sixty years without causing death, as in an instance cited by Gross, but it is more likely to destroy life in from one to five years.

Another instance was reported by Mitchell in the *British Medical Journal* during 1896, in which a half-sovereign is believed to have been in a bronchial tube for twenty-four years without giving rise to any disturbance of the lung, and a piece of bone has been expectorated after being in the lung seven-

teen years. On the other hand, even in those cases where the foreign body is expelled by the efforts of the patient, or removed by a surgical operation, the danger to life is not at an end since an ulcerative or septic process may have been set up, which progresses even after its cause has been removed.

Where the evidences of pulmonary obstruction or septic infection resulting from the presence of a foreign body are positive, the question arises as to whether it is wise to attempt to remove the foreign body from the trachea or through the chest wall. In regard to this point Lendon evidently thinks that we must decide the question in connection with each individual case, although he rather favors exploration through the chest. It is, however, an undeniable fact that the foreign body can often be removed through the trachea by means of a long pair of forceps, but it is interesting to note that Godlee tells us in the *Medico Chirurgical Society Transactions* for 1896 that he performed an operation upon the chest, and opened a cavity in the lung, but failed to find the foreign body. A sinus, however, persisted, and through it the peg of a top dropped out two years later.

Lendon protests against the operation of direct bronchotomy in the earlier stages, as he thinks its difficulties practically prohibit it. He believes that tracheotomy is the only resource and should be done early before obstructive changes occur in the lung, and he insists that inversion should not be practised when a movable body is present, unless the physician is prepared to do tracheotomy at once if urgent necessity arises.

His article concludes with an appendix covering the thirteen cases so far reported in Australia and giving fourteen references to literature bearing upon the subject.

---

#### THE OPERATIVE TREATMENT OF JACKSONIAN EPILEPSY.

---

Braun, of Göttingen, reviews a subject which some years since occupied much time in the proceedings of medical societies, and much space in the periodicals, by the publication of a case of severe Jacksonian epilepsy which was not merely relieved by operation, but which was cured and was still well seven years after the time of the report. As a result of the discussion as to the value of the operative treatment of the affection, the profession at large gathered the impression that the permanent cures were few, if any; that a

minor operation, such as trephining, was as likely to be followed by marked betterment as a major one, such as excision of a portion of the cortex; that even when there were distinct lesions, such as cysts or cicatrices or depressed bony fragments, the ultimate prognosis was bad; that even of the ultimate history of the reported cured cases procured few, if any, would be shown to have been permanently relieved of their epileptic attacks.

Braun's case was that of a man twenty-four years old, who suffered from a head injury of the right side in his twelfth year so severe as to produce immediate paresis of the left upper and lower extremity. Four years later epileptic seizures developed, beginning in the left thumb, then involving the arm, later the leg, not accompanied by loss of consciousness. Two years later the convulsions had become more severe, and during them the patient was unconscious. At the first operation, performed in 1889, depressed bone was raised and the contents of a cyst were evacuated. The extreme tenderness on pressure from which the patient had complained was relieved, but his epileptic seizures were not. Three months later a second operation was performed, having for its object the removal of the thickened tissues overlying the motor center for the hand. This also failed of its object. Eight months later the patient was operated on for the third time, the cortical center presiding over the movements of the left hand being extirpated. With the exception of a few light seizures immediately following intervention, the patient after this remained entirely free from epileptic attacks.

Braun has collected fourteen cases in which the motor center found by electrical stimulation was excised. In four of these there was no improvement, five were distinctly bettered, five were reported as cured; but none of these, with the exception of the one reported by Braun, had been under observation for more than fourteen months, hence the cure cannot be justly claimed, since recurrence of convulsions may occur after two or even after three years. Of five cases in which the center was found by its anatomical position and excised, one failed utterly; the other three were not under observation for even six months. A combined statistical study of the cases in which the center as located by electricity was excised, of those in which it was anatomically placed, and of those in which portions of the brain sub-

stance in the region of the Rolandic fissure underlying the seat of an old tumor were removed, shows that of thirty cases nine were improved and thirteen cured, but that only three of these thirteen cases had been under observation for more than three years. This is not a satisfactory showing, but it may be in part due to imperfect technique. Thus, theoretically, cure can only be expected by the accurate and complete removal of a specific center. This can only be found by the electrical current; one too strong will by diffusion confuse, one too weak will not produce peripheral motion. Braun commends a current of such strength that it is perceptible to the moistened finger and is slightly painful to the tongue; it should not produce motion through the dura. Muscular contractures may be absent when the brain at the point of contact is profoundly altered, or when it has been irritated by strong antiseptic fluids, or when it has been chilled by long exposure, or when it is profoundly anemic; possibly also in profound narcosis. The electrode employed is of platinum, two points separated by an interval of about four millimeters. Unless the electrical localization is employed it is quite impossible accurately to place the desired center, and that this has not been done in many operations is shown by the fact that immediate local palsy is not noted in the reports.

A critical review of published cases seems to show that the popular belief as to the ultimate development of an epileptic status which becomes so confirmed that it cannot be cured or even benefited by excision of the original focus of irritation is not well founded, long-standing cases often exhibiting more marked improvement than those of short duration.

In a tabulation of cases of Jacksonian epilepsy treated by partial operation—*i.e.*, those other than excision of a portion of the brain substance—twenty-three cases are noted as cured out of fifty-seven operated on; but of these twenty-three cases it is to be noted that only three had been under observation for more than three years. In so far as the reports of cases are convincing, they show that the results are much better when the trephine is applied over the wound area than they are when the seat of operation is selected because of its marked anatomical relation with the affected brain center. Among the severe cases in which the dura was not opened, one was definitely cured, the patient having remained free of fits for seven years. The best results were obtained when

the bone was either so thickened or depressed that it apparently produced local pressure effects. There was marked improvement in every one of these cases.

Among the eighty-seven collected cases, Braun finds that the epileptic seizures began by facial twitching in eighteen, by movements of the upper extremity in forty-seven—in twenty-three of these latter by thumb twitchings.

Although this paper of Braun's cannot lead to any definite conclusion, it at least shows that operative cure of Jacksonian epilepsy, though extremely rare, is possible, and also that in cases characterized by bone depression or thickening marked improvement may confidently be expected.

Braun's advice as to the method of procedure certainly commends itself as conservative and sensible. He suggests that when the focal epilepsy has followed a circumscribed skull wound the first operation should be confined to the bone or the bone and dura. Should this fail the more dangerous and more radical procedure—*i.e.*, the excision of the motor center as indicated by the electrical reaction—may be undertaken, the cutting being carried sufficiently wide and to a depth of five millimeters; or when there is a deep depression or a spot exceedingly tender to pressure not placed near the anatomical position of the affected center, the trephine should first be applied over the seat of lesion without regard to the center. If no improvement follows the center may be sought later. When there has been a very extensive wound the trephine should be applied over the involved center.

---

## Reports on Therapeutic Progress

---

### VELANDER'S NEW METHOD OF ADMINISTERING UNGUENTUM HYDRARGYRI.

HOGNER tells us in the *Boston Medical and Surgical Journal* of March 1, 1898, that he desires to present a very interesting case—a pillow-case—which he thinks will be in the future a valuable instrumental means of administering unguentum hydrargyri.

Dr. Edv. Velandér, professor in venereal diseases in Stockholm, Sweden, and head doctor at the great St. Göran's Hospital for venereal diseases in that city, has recently devised this pillow-case for the above named purpose. The writer's own experience in its use is limited to two patients. However, he

has found it so practical, effective, convenient and clean, that he does not hesitate to communicate the facts.

Professor Velandar is well known among the profession for the work he has done in this specialty of our art. The Velandar method of curing soft chancre by heat is widely spread and adopted with or without modifications. His investigations some years ago on the absorption of mercury in unguentum hydrargyri led him to the conclusion that it is mostly, if not entirely, absorbed by inhalation of the evaporated mercury, and induced him to use in the administration of this drug a combined method of rubbing in the ointment and spreading it out on different parts of the body, and later the simple method of only spreading it over the skin. These facts are now well known. This year he has finally given up spreading the ointment over the skin and relies entirely on the application of the ointment to the inner surface of a pillow-case, which is to be fastened about the patient's body, from the neck downward. This method is now so generally accepted in Sweden that it is there almost the only one at present used in the general administration of mercury externally.

The pillow-case is made of cheap cotton cloth. It measures 38 by 54 centimeters (15 by 21 inches), and has ribbons for its suspension over the chest. The ribbons are placed two laterally at each edge, 12 centimeters ( $4\frac{3}{4}$  inches) above the lower corners, and four upward, namely, two opposite each other at the upper edges, 6 centimeters ( $2\frac{1}{2}$  inches) from the corners. The ribbons are about 64 by 1.5 centimeters (25 by 0.5 inches).

The pillow-case is suspended from the shoulders with the external part of its medicated side toward the body—that is, under the clothing—and is held in position by the ribbons which are tied around the waist and over the shoulders down to the waist ribbons. It is worn consecutively for ten days, alternating every twenty-four hours from the front of the chest to the back, fresh ointment being supplied every night without wiping off the old. After ten days a new pillow-case is applied.

Baths are to be taken once or twice a week, the skin under the pillow-case being washed every night.

Dr. Velandar uses, besides this ointment treatment, all necessary local treatment, etc., and with the ordinary attention to the mouth he has not met more stomatitis than usual.

The quantity of ointment used is six grammes ( $1\frac{3}{4}$  drachms), of a strength of two hydrargyrum to four constituents; and, as before said, it is spread every night over the same half of one of the insides of the pillow-slip. The best way of doing this is to spread the ointment over the outside and afterward turn the pillow-case outside in.

This simple treatment is very convenient for the patient, as he can go about comfortably as usual, is not bothered with any pain-taking rubbing, easily keeps himself clean, and at the same time can easily conceal his treatment.

The pillow case method is also very satisfactory for the doctor, as the mercury seems thus to be absorbed quicker, with less irritation.

---

#### THE PRINCIPLES WHICH GOVERN TREATMENT IN DISEASES AND DISORDERS OF THE HEART.

DOUGLAS POWELL in the Lumleian lectures, reported in *The Lancet* of April 9, 1898, thinks that the treatment of acute heart failure may perhaps be best referred to in connection with that acute disease in which it is frequently met and of which it too often forms the fatal turning point, viz., pneumonia, in which disease the invalidating conditions affecting the heart are: (1) Stress of labor; (2) blood-supply and nutrition impoverished and vitiated; and (3) innervation, excited and debilitated by the effects of shock and pyrexia. How are we to meet, and it may be to anticipate, heart failure under these circumstances? This is really the kernel of the problem before the physician in every case of severe pneumonia. All rational treatment of the early stages of pneumonia tends to lessen the blood-pressure in the lungs. It is in the latter stages, towards the crisis, when the lungs are most extensively consolidated, when the nervous excitement of early pyrexia is yielding to exhaustion, and when the blood aeration is most defective, that acute heart failure is apt to supervene. A running pulse, irregular from loss of vagus control, is the first symptom, soon to be followed by edema of the unconsolidated portions of the lungs frothing up through the bronchial tract to produce that ominous tracheal rattle with which we are too familiar—these are the signs of heart failure threatening life.

There can be little doubt that an exhausted nerve center is at the root of most of the cases of cardiac failure rather than mere overstrain from impeded pulmonary cir-

culatation, and there are two symptoms which especially tend to heart failure and are largely instrumental in causing the nerve exhaustion which brings it about, viz., a temperature above 104° F. and sleeplessness. It will be generally noted that the failure comes on suddenly; there may have been one or two preliminary warnings of partial collapse with running pulse and cold extremities, from which the patient may rally, but which are generally followed by more severe and often fatal attacks. At the very commencement of such signs ammonia, which the writer's experience would lead him to infer after a few days of usefulness tends to rather produce cardiac depression, should be changed for a mineral acid, of which dilute phosphoric acid is the best. Some digitalis or strophanthus should be added to the mixture, and strychnine should be given separately either in an extra quantity of stimulant or subcutaneously if the absorbing powers of the patient are at all doubtful. But the most powerful remedial agent is oxygen, since it attacks one of the chief causes of cardiac failure by securing a supply of oxygenated blood to the coronary vessels, and the pulse will be observed to become slower and fuller under its influence. It should be at hand in all severe cases and should be given in good time as an occasional inhalation.

Whilst as a rule we need not in pneumonia attach much importance to a high temperature, in any case where heart failure threatens it must be reduced to a safer level—*i.e.*, by a degree or two—by hot or cold sponging, or, if necessary, by the dripping cold pack.

Another question presses at about this time; it is that of sleep. Most cases of pneumonia get frequent short snatches of "dog sleep," which is all that we can expect and serves to tide them on to the crisis; but who has not witnessed that wide-eyed delirious vigil in pneumonia, and especially in influenzal pneumonia, in which the mind is painfully alert and the senses preternaturally acute, sleep being entirely absent? The writer is in the habit of suggesting help for wakefulness in pneumonia in the form of a small dose of ten or twenty grains of sulphonal taken in hot fluid at 8 or 9 P.M., and with this preliminary a twenty-grain dose of bromide taken at 10.30 is often sufficient to secure some restful sleep. When the temperature is high a single dose of from seven to ten grains of phenacetine may be added to the bromide. When delirium is a marked feature hyoscine in doses of  $\frac{1}{8}$  to  $\frac{1}{4}$  grain sub-

cutaneously and repeated once or twice may be used sometimes with great advantage.

Cases of persistent sleeplessness almost invariably prove fatal with heart failure, a running pulse, the cardiac action becoming at last merely peristaltic as the blood-clot accumulates in the auricles. Bromides, chloral, sulphonal, are almost useless, and with the gathering serum in the tubes one hesitates to give opiates. And yet in these severe cases morphine should be given to secure a few hours' sleep and to give the nervous system time to recuperate and to allow of some restoration of heart power before it is too late. The writer states that he has seen some cases in which death appeared to be averted by: (1) a strong dose of food and stimulant; (2) one-third grain morphine with atropine; and (3) aeration being maintained by the oxygen current being frequently played over the mouth and nostrils for a few minutes at a time. The oxygen may be warmed as it enters the bag by passing it through a coil of tubing immersed in hot water. It has seemed to the writer that strychnine has rather favored this peculiar sleeplessness of patients when utterly exhausted, but its power as a cardiac stimulant is unrivaled, and its use in cases severe enough to lead up to this condition is quite essential, and it may be renewed on the effects of morphine passing.

The remarks just made are applicable to heart failure in pneumonia, and the author has endeavored to indicate the measures that tend to avert it and combat it when present. He has not dealt with the treatment of pneumonia in any other sense, for to treat the vast majority of cases of pneumonia with alcohol, strychnine, oxygen, morphine and the like would be at best like storming a mud hut with Armstrong guns; to use dangerous remedies, in cases which require only the gentlest treatment and careful nursing, is a great blunder. The fatigue of heart that follows such tempestuous periods is sometimes very great. It is partly nerve fatigue and is associated with an often greatly depressed temperature lasting for many days. It is in part also muscular fatigue. The pulse either remains quick and very soft or it may become very slow and vacillating. Patients should always remain in bed until the temperature, which after the crisis frequently descends considerably below the normal, has had at least a sufficient interval to return to or near the normal range, and cardiac and nerve tonics such as strychnine, caffeine and the hypo-

phosphites will prove valuable on convalescence. Exercise must be cautiously resumed, keeping well within the limits of fatigue until heart power is quite restored.

Acute heart failure in other diseases and from other causes requires a similar handling, varied to meet varieties in the case. Attention should be drawn to the great value of oxygen inhalations in the treatment of heart failure in old people due to fatty degeneration of the organ. These cases are characterized by the usual signs of a rather large and feebly acting heart, together with irregularity of rhythm, there being perhaps twenty or thirty beats fairly reaching the wrist, whilst amongst them are twice as many beats which only very imperfectly do so. Cheyne-Stokes breathing is another remarkable symptom in these cases, which is especially apt to supervene after any fatigue and to come on during sleep. This form of breathing bears no direct relationship to the pulse and is probably an associated degenerative neurosis. The employment of oxygen inhalations several times in the twenty-four hours has a decidedly strengthening influence upon the heart, no doubt by sending some extra-oxygenated blood through the coronary arteries, and it also lessens the Cheyne-Stokes breathing and refreshes the patient. Strychnine is the most useful cardiac stimulant in these cases.

#### RATIONAL ETHERIZATION—A STATISTICAL STUDY.

In the *Medical Record* of January 29, 1898, Dr. M. B. BROUNER writes a paper with this title. He summarizes as a deduction from his experience the following:

1. That etherization should be entrusted only to experienced hands.
2. That a special cone is not necessary for successful etherization. The simpler and less complicated the apparatus the better.
3. That the so-called "force method" of etherization is unnecessary, cruel, and oft-times injurious.
4. That vastly better results are obtained by a gradual, quiet administration.
5. That the amount of ether employed should be minimized, preferably given drop by drop after anesthesia has been fully established.
6. That the evil sequelæ are directly proportionate to the amount of ether employed, and indirectly proportionate to the duration of the anesthesia.

7. That the so-called baneful after-effects on bronchi, stomach and kidney are largely overestimated, and in a large degree controllable.

8. That women require a smaller amount of ether, though a longer time to produce anesthesia, than men.

9. That alcoholic subjects require a longer time and a greater amount of ether to produce anesthesia and to maintain it.

#### THE VALUE, LIMITATIONS AND ALTERNATIVES OF TOPICAL APPLICATIONS IN GYNECOLOGY.

DUDLEY, of Chicago, writes in the *Medical Standard* for April, 1898, upon this subject. He believes that the principal procedures in local treatment are the hot water vaginal douche, tamponade, and intra-uterine applications.

1. *The hot water vaginal douche.* The choice of the syringe, frequency of the douche, time and length of each application, temperature of water, proper use of bedpan, position of patient, and persistence in long continuance of treatment, are all essential factors.

The good results of the douche will be realized only by the strict observance of the following rules in its application as laid down by Emmet:

##### ORDINARY METHOD OF APPLICATION.

1. The douche is ordinarily applied with the patient in the sitting position, so that the injected water cannot fill the vagina and bathe the cervix uteri, but on the contrary returns along the tube of the syringe as fast as it runs in.

2. The patient is seldom impressed with the importance of regularity in its administration.

3. The temperature is ordinarily not specified or heeded.

4. Ordinarily the patient abandons its use after a short time.

##### PROPER METHOD OF APPLICATION.

1. It should invariably be given with the patient lying on the back, with the shoulders low, the knees drawn up, and the hips elevated on a bedpan or rubber sheet, so that the outlet of the vagina may be above every other part of it; when the vagina will be kept continually overflowing while the douche is given.

2. It should be given at least twice every day, morning and evening, and generally the length of each application should not be less than twenty minutes.

3. The temperature should be as high as the patient can endure without distress; it may be increased from day to day from 100° or 105° to 115° or 120° F.

4. Its use, in the majority of cases, should be continued for weeks at least, and sometimes for months. Perseverance is of prime importance.

The douche acts as a vasomotor stimulant and as a cleansing agent.

(a) Vasomotor stimulant: Emmet attributes the good effects of the douche to the stimulating influence of the hot water on the vasomotor nerves, whereby the dilated, congested vessels are made to contract, the congestion lessened, absorption of morbid products hastened, and local nutrition improved. The effect is the same as that of massage after the Brandt method.

(b) Cleansing agent: In pelvic inflammation the vagina is a passageway and to some extent a receptacle for pathological secretions which flow into it from the uterus, Fallopian tubes, pelvic abscesses, from the vaginal mucous membrane, and even from the vulva. Unless kept clean the vagina may become an incubator and a distributing point for bacteria. The value of the douche, therefore, as a measure of asepsis, is self-evident. When local disinfection is required, the douche may have in solution some antiseptic substance, such as lysol, carbolic acid, corrosive sublimate, boric acid, salicylic acid, or peroxide of hydrogen.

The indications of the douche are chiefly in the treatment of chronic pelvic inflammation. The power of heat to stimulate and contract the blood-vessels makes the douche useful in case of uterine hemorrhage. The disposition to extend its use to the routine treatment of a wider range of pelvic disorders should be discouraged.

There are constantly present in the normal vagina great numbers of lactic acid bacteria (Doederlein), whose function is to render the vaginal secretion acid and therefore to make it an unfit culture ground for about ninety per cent. of all pathogenic bacteria. The washing out of the normal germs and their acid secretion opens the way for infection higher in the pelvis. For this reason the indiscriminate use of the douche in the normal vagina is of questionable propriety.

2. *Tamponade.* The principal indications for tamponade are inflammation and hemorrhage.

(a) Inflammation: Tamponade in the treatment of inflammation is designed as a means of pressure, as a vehicle for the application of medicinal substances and for drainage. The pressure effect of the tampon is chiefly useful in the treatment of displacements, especially those due to inflammatory causes. This indication is better fulfilled by Brandt's method of massage. As a vehicle for the application of medicaments, the tampon has

become a routine factor in gynecology. It is often used as a carrier of glycerin to cause a watery discharge from the genital tract and thereby to deplete the vessels and overcome congestion. How far the good results attributed to the tamponade are due to the curative forces of Nature or the associated systemic treatment is difficult to say.

A tampon which is left in for more than twenty-four hours becomes offensive and a possible hot-bed of infection. It should therefore be removed on the day following its application. Its common, indiscriminate, routine use should be discouraged. Its therapeutic value has been much overestimated. If used at all, it should be applied daily. One or two applications a week have little value, except possibly that of suggestion. Drainage of the endometrium for endometritis by means of the intra-uterine tampon will be mentioned later.

(b) Hemorrhage: Vaginal hemorrhage may often be controlled by a tight vaginal tampon. It is, however, better to find and secure the bleeding point. Uterine hemorrhage may demand immediate control. The vaginal tampon which is commonly employed is inefficient and cumbersome. In bad cases it usually fails, and the distention of the vagina by a large tampon interferes with the functions of the bladder and rectum and is a cause of great mechanical discomfort. Intra-uterine tamponade is a more practical, comfortable and effective treatment for uterine hemorrhage. It should be in the form of a continuous strip of aseptic or antiseptic gauze about two inches wide. The cervix having been exposed by a Sims speculum and steadied by a vulsellum forceps, the strip is introduced by a slender dressing-forceps or sound. The gauze should be removed daily, as secretions absorbed by the tampon decompose rapidly and become a powerful source of infection.

If elastic pressure is required, fine lamb's wool is superior to absorbent cotton. For other purposes the continuous strip of aseptic gauze is preferable.

3. *Intra-uterine applications.* The permanent arrest of a long-standing uterine discharge by topical applications to the endometrium is seldom accomplished. The treatment as ordinarily applied does not reach the disease, because it is not only not indicated, but is injurious in the vast majority of cases for which it is used. The prerequisites to safe and efficient intra-uterine applications are a proper selection of cases and a clear pathological indication and definite

appreciation of what the treatment is to accomplish.

The proper selection of cases is arrived at by exclusion. This will lead to the exclusion of at least two large classes of cases:

(a) Cases in which the predominant element is local infection, in which there is a distinct purulent discharge from the uterus, and in which the endometrium is an abscess cavity and the uterine mucosa and sometimes the myometrium the wall of this abscess cavity. If there is a systemic element it is relatively insignificant. In such cases direct treatment to the diseased structures is clearly indicated.

(b) In the second class of cases the predominant etiological factor is systemic; there may be some degree of infection, but this is not the essential factor and should disappear with the improvement of the systemic condition. The treatment of such cases would be clearly not local but systemic.

For the so-called infectious cases the value of topical treatment has until recently been much overestimated and its dangers underestimated. The milder intra-uterine treatment, as ordinarily practised, is long, tedious, and useless. Local treatment, mild or severe, if frequently repeated with indifferent aseptic care, often sets up new infection or carries the old infection to deeper structures. This may dangerously involve the parametric lymphatics and veins, the myometrium, Fallopian tubes, cellular tissue, peritoneum, and ovaries.

Intra-uterine applications are usually effective in proportion to their energy. Only those which have the power to destroy the diseased structures are capable of arresting the discharge. In doing this, however, they may destroy the endometrium, injure the myometrium, and reduce the uterus to a cirrhotic-like, cicatricial condition. Sterility and permanent irritability of all the pelvic organs are the natural results. Numerous operations have been devised with but little success to reopen the uterine canal contracted by the prolonged application of such agents. Contrast this condition with that which follows an aseptic curettage. In the latter condition the healthy abraded surfaces are all ready to reproduce a new endometrium. The routine application of strong caustics to the endometrium is prohibited.

A principal mode of action of electricity is by cauterization, although it is said to have a deeper effect on the blood-vessels. Its continued use may arrest the discharge, but

it is open to the same objection as other caustics. Its chief value is in the soft, flabby, hemorrhagic uterus, especially in the endometrium associated with myoma. The effects of electricity are not limited to the diseased tissue, but may include healthy structures. Its immediate dangers are greater than those of aseptic curettage. Generally speaking the method is not approved.

Intra-uterine gauze tamponade has been extensively used for dilatation and drainage in non-operative cases. Increasing quantities of a narrow strip of aseptic gauze are packed into the uterus at successive treatments until the endometrium has become dilated to a diameter of one-third or half an inch. Such dilatation is said to permit easy and thorough intra-uterine treatment and drainage, especially capillary, when the gauze is in place. The method in the writer's hands has been occasionally successful, but great care is necessary lest the gauze, instead of carrying out septic material, carry it in.

Innumerable drugs and chemicals have been lauded for intra-uterine medication. Carbolic acid and iodine probably meet the requirements in glandular endometritis so far as topical treatment can meet them. In interstitial endometritis ichthyol, although useful, has not entirely fulfilled its early promise.

When the disease is distinctly infectious and chronic, topical and systemic treatment are both inadequate, although both may properly supplement surgical measures. The diseased portion of the endometrium must be removed by the sharp curette. If this operation is thoroughly performed so as to remove the most infectious portion of the endometrium, it is relatively free from danger, offers a reasonable prospective relief, and the curetted mucosa is rapidly reproduced.

The treatment of infectious endometritis, even with the curette, is not uniformly successful. Dilated and obstructed blood-vessels cannot always be restored to their proper caliber; disorganized lymphatics, nerves and glands cannot always resume their normal functions; and regeneration of lost structures is not always possible. In the glandular forms of endometritis the sharp curette offers both a symptomatic and histological cure, but when the disease has progressed to the atrophic stage and the endometrium is physiologically destroyed, only a degree of symptomatic cure is possible. When the endometritis is complicated with extensive chronic

and obstinate pelvic infection, the uterine discharge will persist regardless of curettage or any other intra-uterine treatment, and hysterectomy may be the only way of relief.

The danger and uselessness of topical treatment for the strongly infectious cases is so manifest that few scientific physicians to-day place great value on its use. The situation is, however, quite different in the second class of cases, in which certain systemic conditions are not only the predisposing but the essential etiological factors. These conditions find their chief expression in stagnation of the general circulation; the stagnation is usually associated with disorders of the heart, lungs, liver, and kidneys, and is often found with the uric acid and other diatheses, such as anemia, leucemia, chlorosis, diabetes, gout, and rheumatism. The discharge may come also as a sequel of some acute infectious disease, such as enteric fever, scarlatina, or diphtheria. Not only the endometrium but the mucosa of other organs share in the general condition and become less resistant and consequently more liable to infection.

The uterine catarrh is sometimes apparently a vicarious act. The writer has frequently noticed the cessation or material diminution of a fetid uterine discharge upon reestablishing of the normal functions of the bowels and kidney. Inconsistent as the statement may appear, topical treatment in this class of cases, which clearly do not call for topical treatment at all, has commonly been followed by the best results.

When diligent use is made of topical applications and a cure is effected, it is quite natural to give the credit to that treatment, when in reality the cathartic pill perchance may deserve it; or, in other words, a case of this class may recover in consequence of the proper systemic treatment of the curative forces of Nature, in spite of the associated topical treatment which it did not need and which may even have done harm.

There is a common impression that severe infectious cases should be treated surgically, and that mild, non-infectious cases should be treated by topical applications. The writer takes exception to the latter part of this statement, and says that those cases that are not surgical are generally medical. The endometrium has suffered a vast amount of sometimes mild, generally useless, oftentimes destructive, topical treatment. The uterus has endured an immense amount of abuse, and the absurdity of topical treatment to the

endometrium in such cases is evident when we consider that the uterine catarrh is only one of many local evidences of a general condition. A large proportion of the cases belong rather to internal medicine than to gynecology.

---

*AQUEOUS EXTRACT OF SUPRARENAL  
CAPSULE IN OPHTHALMIC  
PRACTISE.*

KYLE, of Marion, Indiana, reports upon this subject to the *Ophthalmic Record* for April, 1898.

The physiological effect of the extract of suprarenal capsule, when injected into the system or applied locally to the mucous membranes, is as yet imperfectly understood. The chemical nature of the aqueous substance of the capsule is conflicting and indefinite, and the writer states that he is unfortunate in not being able to secure a definite formula. The researches of Gourfein of Geneva, Shaffer and Oliver, and Swale Vincent have gone far to place the extract upon a solid therapeutic basis.

"In the adult the glands are triangular in shape, weighing from one to two drachms, having a cortical and medullary portion, the cortex forming a yellowish shell around the dark red or brown medulla."

Swale Vincent reports a marked physiological difference between the extract made from the medulla and that from the cortex of the sheep or hog. The extract from the medullary portion when injected into mammals was invariably fatal, while that from the cortical portion had no physiological effect.

The powder and extract supplied to the trade is known as saccharated suprarenal gland, twelve grains representing one fresh suprarenal gland. The extract when used in from two- to four-per-cent. solution is a powerful astringent, and in the writer's experience there is no remedy in the oculist's armamentarium that is capable of producing such a remarkable effect. The writer has experimented with the drug in a great number of cases during the past year, and has had no ill-results.

Dr. W. H. Bates, of New York, read a paper before the Section of Ophthalmology of the New York Academy of Medicine, on April 20, 1896, and referred in a concise and interesting manner to the wonderful therapeutic effect of the extract. When used in the eye, nose or throat no smarting or irritation is produced. In the eye there is a sense of

coolness, with no mydriatic or mycotic effect. The conjunctiva, regardless of congestion, turns suddenly pale, due to contraction of the coats of the vessels, and remains so from one to two hours. Nor do we, as verified by Dr. Bates, notice any congestion after the astringent effect has subsided; the conjunctiva, furthermore, manifesting no intolerance from long use of the drug. We notice when applied to the mucous membrane of the nose and throat the same astringent effect as that seen in the eye. For this reason it is especially indicated preliminary to operation upon the turbinates or upon the septum, first, because it has such a decided hemostatic effect; secondly, it prolongs and increases the effect of the cocaine. Furthermore, the writer has found in operations upon the nose, when he has used the extract preliminary to cocaine, that he has been agreeably surprised at the very small amount of cocaine necessary to secure complete anesthesia, and the very little hemorrhage accompanying the operation.

In operations upon meibomian cysts, complete anesthesia of which under cocaine is, as we know from experience, difficult to secure on account of the great vascularity of the parts, we will find by using the extract as indicated that the operation can be done with remarkably less pain than when cocaine is used alone.

The extract is especially indicated in cases of chronic trachoma, characterized by marked vascularity and lacerimation, in pannus, lacrimal inflammation, acute conjunctivitis, panophthalmitis, and iritis. Again, in operating upon the lacrimal duct, complete anesthesia is procured by injecting a few drops of the extract preliminary to the cocaine; the result is so complete that no one should hesitate to give the drug a thorough test.

Care must necessarily be taken in preparing the solution and keeping it thoroughly sterilized. From the nature of the extract we expect it to rapidly deteriorate. To preserve the solution, in addition to frequent sterilization the writer adds a few drops of carbolic acid, or two drachms of an already prepared two-per-cent. phenic acid solution. This makes no chemical change and is one of the few germicides that can be used with the extract. Mercury bichloride cannot be used; when added to the extract it gives a pinkish color, and upon heating turns to a dark red. Frequent sterilization will not alter its physiological effect. It is wise, however, as far as possible to prepare fresh solu-

tions. To do this we take twenty grains of the saccharated gland and a two per-cent. solution of phenic acid; mix, and filter through filter paper. We now have a clear solution of a brownish-red color, which must be kept corked and free from light. Two or three drops in the conjunctiva produce a complete astringent effect. When applied to the mucous membranes of the nose or throat we secure similar results.

In conclusion the author enumerates the variety of cases in which he has used the extract with decidedly beneficial results, both as a hemostatic and as an adjunct to cocaine: Acute conjunctivitis, chronic granular conjunctivitis, operation for the removal of turbinates, exostosis of the septum, polypoids of the nose, pterygia, meibomian cyst, operations upon the lacrimal duct, removal of necrosed ossicles, and curettement of the attic.

#### THE TREATMENT OF HEMOPTYSIS.

*Treatment* of April 14, 1898, contains an article by SAINSBURY on this ever interesting subject. He begins by telling us that to secure local rest to the chest the patient must not talk, except when absolutely necessary, and then must not raise the voice; that the attendants must not whisper, and above all, there must be no whispering outside the door lest alarm reenter.

A little broken ice to suck occasionally will be of value as an assurance to the patient that something is being done, and a reminder that the patient is under treatment.

The treatment of cough will be more important; it will demand attention at once, and by morphine or opium in some form or other it must be reduced to a minimum.

Here we may mention the value of a hypodermic injection of morphine. This, as Douglas Powell insists, is very serviceable in cases of large hemoptysis attended by much shock and alarm, composing as it does the nervous system generally, and so quieting and regulating the circulation; it will, moreover, check any disturbing cough. Opium, then, or morphine, by the mouth or hypodermically, will be perhaps the first consideration after the securing of rest.

The bowels will next claim attention. It is well recognized that constipation is liable to be attended by a raised blood-pressure, and that a brisk purgative will quickly remove this tendency; if, therefore, the patient be constipated, some purgative—best a saline—should be administered. Even in the ab-

sence of constipation this treatment is beneficial. A quiet, well ventilated room, cool as to temperature, and the above simple measures will secure for the patient favorable conditions. The nourishment should be very bland and unstimulating, and liquid (for one reason because of the ease of administration). Milk cannot well be improved upon; it should be taken cold or cool. Alcohol must be avoided as far as possible, but our hand may be forced if the collapse be extreme.

And now to consider more active treatment. It is admitted that we cannot get directly at the bleeding point, but can we indirectly by the reflex arc reach the bleeding area? Can we throw a stimulus from the surface, external or internal, on to the vessels of the lung?

Bradford and Dean's investigations have shown that the lesser circulation is under vasomotor control, but Osler is right in stating that as yet our knowledge on this subject is very imperfect, and in particular in respect of the relationship between the blood-pressures in the systemic and pulmonary circuits. Still we act upon the theory that we can influence the vessels of the lung by surface stimulation, and so far as the mucous membrane of the trachea goes, Rossbach's investigations seem to furnish proof of this. Accordingly we may apply to the chest the ice-bag, or we may apply very hot flannels, the stimulus yielded by either extreme acting probably in a similar manner. Should the application be continuous or intermittent? This is an important point. Rossbach's experiments showed that the blanching of the mucous membrane of the trachea caused by the external application of cold was not maintained with the prolongation of the application, but gave way to a congestion, venous in type. On this ground, then, as also on the grounds of common sense, which would urge that to get a reflex the nerves upon which we are acting must be neither benumbed by cold nor exhausted by heat (if we use the latter), we should employ temperature extremes intermittently. We may reasonably, then, apply the ice-bag to the chest of the patient for half an hour at a time, at intervals of half an hour or an hour. We would suggest that in cases of extreme collapse the hot application similarly applied might with advantage be substituted.

Counter-irritation by fly-blisters or the mustard leaf is a perfectly safe, and in some cases apparently an efficacious, treatment. The mode of action will be doubtless in part

by a reflex, in part perhaps by the surface, filling of the vessels of the skin. If the latter action does play an appreciable part, the larger the area of stimulation the better. Dry cupping is sometimes applied; its mode of action will be principally derivative, by the filling of the vessels of the skin and of the integuments generally.

Without disturbing the patient, and with satisfaction to him, and without any likely interference with other treatment, the ice-bag may be applied, or the hot flannel, or the counter-irritant, or the dry cup—there is no complication in all this, and the moral effect upon the patient is undoubtedly good.

Thus far the patient has had no medicinal treatment, if we except the hypodermic injection of morphine or the cough lincture, and possibly the aperient, all of which treatments are not of routine but as occasion may direct.

Now, do we possess any drugs which can control bleeding from the lungs? Here we come to the parting of the ways—the oracle of Apollo emits an uncertain sound. Our choice lies in two directions: On the one hand the pointer indicates drugs such as ergot and digitalis, which contract the arterioles and raise blood-pressure; on the other hand, it directs us to drugs such as aconite and to nauseants such as ipecacuanha, which dilate the arterioles and lower arterial pressure.

Theory can justify the use of either, inasmuch as hemorrhage depends on two factors, viz., the rent in the vessel or vessels, and the plus pressure on the same. Contract the vascular area in which is the bleeding point and *ceteris paribus* the escape must diminish; lower the general blood-pressure, and again, *ceteris paribus*, the bleeding must diminish. But the *ceteris paribus* cannot be granted, for at the same time that aconite lowers the blood-pressure it leaves a more lax open state at the periphery—a more open door; and at the same time that digitalis contracts the periphery it raises the blood-pressure, thereby increasing the escaping force. So far as theory is concerned, the whole question turns upon the position of the bleeding point; if this be in the capillary area or in the terminal arterioles, then theoretically the use of the digitalis and ergot group is eminently reasonable, for the local contraction is likely to outweigh in effect the general rise in blood-pressure—but if the bleeding be from a vessel of size, and a portion of that vessel be aneurismal, then the use of digitalis and ergot is most irrational, for the

area of contraction will not include the bleeding point, and the rise of blood-pressure, it would seem, can only favor the bleeding.

To apply these considerations the first need is of a better diagnosis—the possibility of distinguishing between a capillary or an arteriole oozing and a hemorrhage from a vessel of size. Osler says: "When the blood is brought up in quantities—in mouthfuls at a time—it is almost certain either that an aneurism has ruptured, or that a vessel has been eroded." This is too sweeping, for Fagge's case of miliary tuberculosis with no gross vascular lesion proves that without such the hemorrhage may be copious and even fatal, and some of the cases of phthisis ab hæmoptœ have shown an abundant hemorrhage as an initial symptom with no physical signs of gross pulmonary lesion. It will be best, therefore, to qualify Osler's statement by the addition: if the case is of long standing clinically, or is accompanied by well-marked physical signs. In such case theory would say, "Withhold ergot and digitalis." But if the case be one of large hemoptysis as an early or initial symptom with few or doubtful physical signs, theory would confirm the use of ergot, for the bleeding is probably from small vessels.

The truth, however, is that we are not yet in a position to treat hemoptysis scientifically in respect of these two classes of drugs, and that whilst we must make every endeavor to be more precise in the reasons for our selection, at present the choice is more or less a random one. On the whole, there is a general agreement that in severe cases of phthisical hemorrhage of all kinds, ergot is perhaps the most reliable drug, administered in full dose, initially, of the liquid extract (two to three drachms), and afterwards in smaller dose of twenty to thirty minims every hour for a few doses (Douglas Powell); or hypodermically in full dose, fifteen minims of the official solution of ergotin (Bonjean), or ergot aseptic—equals four to five grains of ergotine. The hypodermic injection is the more potent agent; it should be made deeply into the muscles. The subsequent action may be maintained either by injections or by doses of the liquid extract, say twenty minims every half-hour for a few doses.

The use of digitalis is indicated in the same class of cases as that which calls for the use of ergot, but we do not know that it possesses any superiority over ergot, and in general it is a drug which develops its effects slowly. Whitla thinks it is useless in an emergency,

but excellent where the hemoptysis is not large, but persistent. If employed as a means of controlling a sudden large hemorrhage it should be given hypodermically, twenty to thirty minims of the tincture, the dose to be repeated in half an hour if need be. Wood states that thus given its action develops rapidly. Tincture of hamamelis is certainly useful in hemoptysis, and may succeed when other remedies fail. It is indicated in cases of small but persistent blood-spitting. We are quite in the dark as to its mode of action. Hamamelis may be given in ten- to twenty-minim dose every four or six hours, or the distilled extract of witch-hazel may be given up to two drachms twice or thrice daily, or in more frequent smaller dose.

The use of astringents, *e.g.*, gallic or tannic acid, or of alum or subacetate of lead, is a routine treatment with many. In employing such we must not forget Whitla's advice that in urgent bleeding the remedy must be repeated frequently, and the initial dose be maximal, *e.g.*, of gallic or tannic acid twenty or thirty grains, in one ounce of water, at once, and subsequently a teaspoonful of such solution every twenty minutes. Astringents will tend if anything to raise the blood-pressure, and therefore will associate themselves rather with ergot and digitalis, and both treatments may be combined. If lead be employed, its tendency to lock up the bowels must be watched and corrected. Quite in the opposite direction lies the treatment of hemorrhage by such drugs as aconite and nauseants, yet these have their advocates. The mode of giving aconite will be small and frequently repeated doses, but we have more knowledge of the use of ipecacuanha and of antimony in nauseant or emetic dose, and amongst those who have strongly advocated this method is Trousseau, who has thus revived the practise of Cullen and Willis, of Stoll, and of others. Dujardin-Beaumetz, who also admits the value of this treatment, keeps it in reserve as a last resort. Trousseau's method was to give ten to fifteen grains of powdered ipecacuanha every eight to ten minutes for some four to six doses, so as to cause strong vomiting; he would repeat this treatment without hesitation subsequently if need were. A modification of this treatment, adapted to milder cases, is to give the drug in nauseant dose only, *e.g.*, two grains of ipecacuanha every ten minutes.

Common salt, which is recognized as a remedy in hemoptysis, acts probably in the

above way; it should be given in one-half to one or two teaspoonful dose dissolved in a very little water; the dose to be repeated till the patient is nauseated.

Here venesection may find its place, a remedy which has at times seemed to control the bleeding in very severe cases. There is no more potent means of lowering blood-pressure. This and the emetic or nauseant treatment will be more clearly indicated in proportion as the patient is more full blooded and the circulation more excited.

The application of firm ligatures around the thighs and the upper arms appears in some cases to have been effective; the *modus operandi* is perhaps by starving the pulmonary circulation by the arrest of the blood returning from the limbs. If this be the explanation this method also will secure a lowered blood-pressure.

To conclude this brief sketch Sainsbury refers to a more recent method which attacks the problem from quite a different point of view. It seeks neither to close the rent in the vessels nor to reduce the blood-pressure, but to heighten the coagulability of the blood generally, and so to favor thrombosis at the bleeding points. This is the treatment by chloride of calcium, which, based on physiological findings, has been developed chiefly by Professor Wright, of Netley. The salt must be given in full dose, fifteen to forty-five grains every four to six hours, or in great emergencies twenty to thirty grains, as an initial dose, and then four to five grains every quarter of an hour for a few doses subsequently, as above. One point of importance must not be omitted. Professor Wright's investigations have seemed to indicate that the coagulability of the blood increases during the chloride of calcium administration up to a certain point, and then declines and may fall even below the normal. Should this be established it will be necessary to administer the salt intermittently. For three or four days the coagulability increases, according to Wright; therefore, during a period not exceeding this, the drug may be given, dissolved either in water or milk, or with the addition of some compound extract of licorice. Chloride of calcium is thus employed at the Victoria Park Hospital.

---

*THE TREATMENT OF POISONING BY CARBOLIC ACID.*

*La Presse Médicale* of March 19, 1898, tells us that LANDOUZY gives the following

directions as to the treatment of this condition: Inject immediately by hypodermic syringe thirty to sixty minims of sulphuric ether as a stimulant. Use a rectal injection of two ounces of sulphate of sodium in three pints of filtered water, irrigating the bowel as high as possible after the manner of Cantani. Administer by the mouth or by means of an esophageal tube one ounce of sulphate of magnesia in a quart of hot water, as this will form an innocuous sulpho-carbolate with the carbolic acid. It may be necessary, also, to bleed the patient and then to perform intravenous transfusion or hypodermoclysis, the injection consisting of 300 grains of chloride of sodium in a quart of boiled distilled water. Morphine and heat should be applied to the extremities, and if the fluid which has been injected into the rectum to wash it out has passed away, a small injection of strong black coffee should be given as a respiratory stimulant. Tea and hot punch may also be administered.

---

*A NEW OPERATIVE TREATMENT FOR HEMORRHOIDS, WITH REPORT OF CASE.*

J. K. SIMS in the *Maryland Medical Journal* of May 7, 1898, tells us that having made a careful study of the various operations that have been adopted for the radical cure of hemorrhoids, he finds them all subject to various objections, viz., they leave a stump that must slough off, or an open wound that must heal by granulation. This, in a location like the rectum, which cannot possibly be kept aseptic for any length of time, must naturally be a slow process, and in addition to this there is the possibility of serious systemic poisoning should these open wounds become infected with pathogenic microbes. Again, wounds that heal under suppuration leave a great amount of cicatricial tissue to contract and distort the organs.

The operation which the writer proposes, if properly done, will to a great extent overcome these objections. It takes more time and care and is more difficult to perform, but the advantages gained by the patient more than compensate for this additional work. Of course, it may not be applicable to every case, but with suitable modifications it may be made applicable to the majority of cases of both internal and external piles, as well as to polypi and other benign neoplasms of the rectum and anus.

The patient should have a gentle mercurial

purgative on the two evenings previous to the day of operation and a saline each morning before breakfast. This will clean out the bowels and open up the portal circulation, so that we can give the rectum a long rest afterwards. The circum-anal region should be shaved and scrubbed clean and the rectum washed out with a large enema of warm soap-suds or carbolized water. A warm bath is given and clean linen put on. The anesthetic is now administered, after which he is placed in either the lithotomy or the Sims position. Then introduce a speculum (Cook's and Mathews' are the best) and divulse the sphincters as widely as the instrument will distend them. Then with the thumbs still further stretch until completely paralyzed. The piles will now present themselves, but not in their entirety; they should be everted as much as possible and the rectum and circum-anal region well irrigated with a 1-to-2000 mercuric chloride solution. The tumors, one by one, are now caught with four-pronged forceps, pulled out, and held by the assistant; then with a sharp scalpel the mucous membrane is cut through, around the base of the pile, and a silk ligature tied tightly (in the groove made by the incision), including only the blood-vessels and connective tissue. The pile is then cut off close to the ligature, leaving only enough to hold it, and the cut edges of the mucosa are brought together over the stump with continued sutures of catgut. If the tumor is large, with a curved needle pass a double suture through its base and ligate it in two portions; then the mucous membrane is sutured as above.

If there are external piles present also, the same method may be used to remove them, if large and vascular, or if due to a thrombus; but if they are small or are much indurated they may be simply cut off close to the skin, any bleeding points caught with forceps and ligated, the cut edges brought into close apposition with interrupted sutures of silk. The field of operation is again irrigated with a hot bichloride of mercury solution, the parts dusted with iodoform or aristol, the mucosa pushed in well and a small piece of iodoform gauze inserted, leaving the end protruding from the anus. A pad of gauze is placed over the anus, and over this a pad of absorbent cotton is bound firmly with a T-bandage. A hypodermic injection of morphine  $\frac{1}{4}$  grain, with atropine  $\frac{1}{16}$  grain, is given and patient put to bed.

The bowels should not be moved for three

or four days, by which time the wounds should be nearly healed; they should then be moved by salines and enemata. The advantages claimed for the operation are that by leaving only closed wounds, made under antiseptic precautions, we lessen the risk of suppuration and perhaps more serious infection; that they heal in a much shorter time and with less pain and suffering; there is less danger of hemorrhage and of distortion, and perhaps neuralgia, of the rectum, from contraction of the cicatricial tissue.

In regard to external piles the writer emphasizes the advice given by Dr. Mathews in his admirable work on the rectum: "Remove all of the tumor, cutting it off close to the skin," instead of merely snipping off a small portion of it, as is advised by most authors. If small ones are left they are apt to become inflamed, and they, as well as the stumps left, tend to get much larger, often necessitating another operation to remove them.

#### THE TREATMENT OF INCOMPLETE DEVELOPMENT OF THE UTERUS.

The *Brooklyn Medical Journal* for May, 1898, contains an article by A. J. C. SKENE on this topic. As he well says, cases of flexion of the uterus are unfortunately rarely seen during the stage of development. The condition is usually well established before the patient presents herself to the surgeon or physician. More than that, the other complications that are so sure to follow this malformation are usually established before they come under our professional care—that is, general pelvic hyperemia and catarrhal endometritis, conditions or affections which are developed from the deranged innervation and circulation, pain and suffering that arise from or are caused by the malformation and consequent dysmenorrhea. It is also a common thing to have (in addition to the general hyperemia of the uterus and a catarrhal endometritis, or it may be adenomatous corporeal endometritis as well) ovarian hyperemia, that in time is likely to run into chronic ovaritis. When such patients can be taken in hand before these complications are established, and the age of the patient is favorable, say anywhere between fifteen and twenty, they can usually be completely relieved; not only that, but they are likely to remain perfectly well. In such cases, when their history is sufficiently clear to enable one to make a diagnosis with a certain degree of positiveness, he prefers to anesthetize,

and then complete the diagnosis and employ the treatment that may be called for.

In the first place, the author states that the most absolute cleanliness and asepsis should be observed in the management of these cases, and when there is no opportunity to cleanse the parts by douches and bathing before the patient is anesthetized, then that thorough cleansing process should be carried out during the anesthesia. Then the examination should be made, the form of flexion clearly made out, and the treatment adapted to the condition found. For example, in case the uterus is found to be rather lax or soft of tissue and the flexion is limited to the body of the uterus, and there is menorrhagia, as there often is in those cases, then the treatment should be moderate—rapid dilatation, curetting to remove any hypertrophic or adenomatous tissue that may exist there, and washing out the uterus with a solution of carbolic acid, glycerin, and water. The dilatation should be to the extent of three-quarters of an inch, or less, say half an inch, according to the size of the uterus; then in place of packing, as recommended by some, he employs a drain, which also acts as a splint—that is to say, a piece of gauze as large as can be admitted into the dilated canal, well twisted and carried up to the fundus uteri and then cut off short at the os externum. This is allowed to remain and keep the uterus in proper shape as long as it is tolerated. The moment that any irritation occurs, indicated by elevation of pulse or temperature, it is to be removed, and if the uterus is disposed to fall back into its flexed form, the packing should be repeated. The packing with the twisted gauze acts not only as a drain but as a splint, and is usually quite sufficient to keep the uterus straight in those cases of soft-tissued uteri and in forward flexion of the body of the uterus alone.

When the flexion forward is confined to the body of a uterus that is unusually dense in structure (and these are the most troublesome cases, because the dysmenorrhea is almost always severe), the treatment is conducted upon the same principles, but carried out in a somewhat different way. In these cases the tissues are so dense and unyielding that unless the greatest possible care is taken there is great liability to laceration of the inner structures of the body of the uterus, and also of the lowest portion of the cervix. When a dilator is used that is too short, the blades of which dilate in a parallel way, if they do not extend to the fundus or near to

the fundus the points of the blades are liable to become embedded in the walls of the uterus, as dilatation goes on, and do very great damage. Very great care should be taken to make the dilatation equal from the os externum up to the entrance of the Fallopian tubes. More than that, it is necessary in these cases to make the dilatation greater in a uterus of dense structure. Of course, the degree of dilatation must depend upon the size of the uterus. Often the uterus is small and dilatation to the extent of half or five-eighths of an inch is as much as can be employed, whereas in a larger organ dilatation to an inch or less might be equally well tolerated. While the dilatation is done under an anesthetic and is completed in the shortest period of time, yet it should be conducted very slowly and gradually, watching carefully that the tissues are stretching and not being lacerated. In case the misfortune of laceration does occur, in spite of all care, the cases usually do badly, or at least not as well as if that accident had been avoided. After the dilatation has been completed, in the same way as in the other condition just described, the same drain is introduced and allowed to remain as long as it is agreeably tolerated. It is repeated again if the uterus is inclined to fall back into its former position, although in all cases of that kind it is impossible to introduce as large a piece of twisted gauze as the first was. In the great majority of these cases there is usually amenorrhea or scanty menstruation, and hence it is not necessary to use the curette, but simply to use the gauze in the way already described.

In the majority of cases just described the treatment here given is sufficient, but if at the next menstrual period there is still dysmenorrhea, and on examination it is found that the flexion has returned in part or entirely, then it is necessary to employ the stem pessary for a time until the tissues at the weak point shall regain their strength and increase in quantity. The stem pessary which the writer employs is the glass rod with a flange at the end of it, choosing one that is long enough to extend up to within about a quarter of an inch of the fundus uteri, and holding it in place by a Peaslee's ring pessary closed in on one side so as to form a cup. A soft-rubber pessary is more easily introduced because it is flexible, and it is more easily borne, and by the use of the douche it can be kept reasonably aseptic, provided it is thoroughly coated with white vaselin before it is introduced.

While the patient is wearing this kind of

support it is very necessary that she should be under continual observation, and that is one argument in favor of treating these patients in hospitals, where they can be closely watched. The writer refers to the fact that many have permitted patients to go around about their usual duties or occupations wearing stem pessaries, but he has never dared to take such risk, and for that reason, perhaps, he has never had any very serious accidents follow their use. Last summer he saw a lady in the mountains suffering intensely from a pelvic inflammation caused by a stem pessary introduced by a New York practitioner who has repeatedly claimed in his writings that he is the most successful surgeon in the business.

In regard to the class of cases now under consideration—that is, forward flexion of the body alone, uncomplicated with endometritis, or ovaritis, or anything of the kind—this treatment is usually sufficient to relieve the dysmenorrhea and overcome the sterility in the majority of cases. The writer was quite surprised to find how many of these patients were cured of their sterility; and yet some, quite a number in fact, have not been cured. There are others who keep well for a time and then the dysmenorrhea returns. This is especially so in cases of the hard or dense-structured uteri, and especially if there are some rudimentary small fibroids in the walls of the uterus. These cases are the most difficult to cure, and they are most likely to have a return of their trouble. The others are much more satisfactory in this respect.

#### AMPUTATION OF THE PENIS; DESCRIPTION OF A NEW TECHNIQUE.

RAMON GUITERAS, in the *Journal of Cutaneous Medicine and Genito-Urinary Diseases* for May, 1898, writes on this topic, and states that it is his purpose to speak simply of anterior operations, and not the so-called extirpation where the whole organ is removed and a urethral orifice is made in the perineum.

Many methods of performing this amputation have been devised, which tend to show that, although the operation is a simple one, surgeons are not as yet satisfied with the results.

These operations differ principally in the methods advocated of making the flaps, and in the instruments used. In the first instance some operators recommend the circular, the antero-posterior, or side flaps, while others

have advised no flaps at all, excepting what can be obtained from the redundant tissue. In the second instance amputation is performed by means of the ligature, the *écraseur*, the galvanic cautery, the galvanic *écraseur*, or the knife.

Many authors have written upon this subject, among whom are Sir William Ferguson, Pearce Gould, Bonner, Erichsen, Humphrey, Earle, Teale, Demarque, Hilton, Treves, Bryant, Stimson, and Bell. Most of these surgeons seem to agree upon one point, and that is that the urethra and the skin should be allowed to remain longer than the corpora cavernosa. They have not, however, mapped out any systematic operation, and for this reason it is the author's purpose to outline the one which he has been in the habit of teaching at the post-graduate school during the last few years.

Before entering into this description it might be interesting to consider briefly the principal difficulties attending this operation that make it so unsatisfactory. They are:

1. Hemorrhage.
2. Retraction of the orifice of the divided urethra within the stump.
3. The narrowing of the orifice by the contraction of the superficial tissue.
4. The wetting of the wound by the urine.

To overcome the first of these, namely, hemorrhage, it is necessary to tie a rubber band or an elastic catheter about the base of the organ until the amputation has been completed, when the dorsal arteries and those of the corpora cavernosa should be caught and ligated with catgut. Any further hemorrhage can be controlled by hot water, peroxide of hydrogen, and the pressure made by the dressing on the flaps.

In regard to the second of these difficulties—the retraction of the orifice of the urethra into the stump—this can be guarded against by cutting the urethra at a lower point (nearer the meatus) than that where the penis is amputated. This is quite generally advocated, and it appears to be the general consensus of opinion that one-half inch is the excess in length to be allowed.

The third difficulty is the narrowing of the orifice by the contraction of the superficial tissue. This is probably the most serious obstacle that the surgeon has to contend with, and operators often try to overcome it by slitting up the lower wall of the urethra and then stitching its mucous membrane to the skin. This certainly makes a large orifice, but the urethra above the point

to which it has been incised is more or less distorted, so that a stricture is liable to occur there, as is the case with most other devices that have, up to the present time, been resorted to. Such a stricture or contraction is even worse than a simple contraction of the orifice, as it extends half an inch or more into the anterior urethra. It seems, therefore, that if the end of the cut urethra protrudes sufficiently and is then well united with the adjoining skin, a better formed meatus will result, and if a stricture of the orifice does take place it can easily be treated by a meatotomy, followed by a dilatation, as in any other case of contracted meatus.

In regard to the fourth difficulty—that is, to the wetting of the parts by the urine—this is a hard matter to remedy, and always interferes with the healing and union of the approximated edges. The best way of overcoming that difficulty is by means of a soft-rubber catheter, which should be passed into the bladder and allowed to remain there for several days. A retained catheter is, however, in every instance objectionable, as independent of the danger of wetting the part with the urine and the urethral fever it may occasion, the pressure it exerts upon the united surfaces tends to cause a slough about the stitches. It is, therefore, hoped that some method will soon be discovered which will supplant that of catheter-drainage in these cases. If any urine does succeed in wetting the united surfaces it should be immediately washed away and the parts cleansed with a boric acid solution.

The method of operating presents no new features when considered *in toto*, but is of a more careful technique than any which has been described heretofore. It is briefly as follows:

The parts having been thoroughly cleansed after the methods of to-day, a rubber band or catheter is tied about the base of the penis, and a circular incision is made through the integument of the organ at a point below the growth where it is healthy. The skin is then dissected back for three-quarters of an inch, thus making a flap, which is rolled upward toward the base of the organ. A sound, about a No. 20 (French) in size, is then passed into the urethra, and held by an assistant in such manner that the penis is at a right angle to the body.

The blade of a straight bistoury is then inserted with the cutting edge pointing upward at the point to which the flap has been rolled, and is worked in between the urethra and

the corpora cavernosa until it comes out at a corresponding point at the other side. The blade is then turned toward the corpora cavernosa and is made to cut through them. The corpora cavernosa are then taken between the fingers of the left hand and traction is exerted upon them while they are being dissected away from the urethra for the distance of one-half an inch. The cutting edge is then turned toward the urethra and, the sound having been withdrawn, it is cut through at this point.

Thus we will see that the operation, as far as it has advanced, consists of an amputation through the anterior part of the organ in such a way that the stump or divided corpora cavernosa has a urethra half an inch longer than itself, and an integumentary flap three-fourths of an inch longer.

The two dorsal arteries and the two arteries of the corpora cavernosa are then caught and ligated with fine catgut, also the small artery of the septum, if present, and any oozing of blood is controlled as well as possible by peroxide of hydrogen or hot water.

The margins of the cut integument at the upper and lower surfaces of the organ in the median line are then caught with the thumb forceps, and traction sutures are passed through each of them at these points, and held by assistants.

The urethra is then caught in the same way above and below the median line, and traction sutures are also passed through it and held by assistants in such a manner that the middle of the cut surface of the urethra corresponds to the junction of the lower and middle third of the cut surface of the integument.

A fine silk suture is then passed through the integument and urethra at each extremity of the canal, passing entirely through the walls of the integument on either side, but only through the walls of the urethra and not through its lumen. These are then tied, thus holding the urethra and skin in place in the relations already mentioned. The integument above and below the urethra is then united by interrupted sutures.

After this, four sutures of fine silk are passed through the integument and the urethra, piercing the lumen. They are then pulled up in the middle and tied on either side. Thus we will see that the skin and urethra are held together by ten sutures, four on each side and one on each extremity, well placed with thorough approximation.

The parts are then washed with sterilized

water and the traction sutures are withdrawn, thus leaving a stump. A sound is then passed through the new canal into the bladder, after which a No. 10 French catheter is passed into the viscus and allowed to remain there for a few days.

The wound is then dressed with iodoform gauze and the catheter is held in place with a piece of adhesive plaster attached to the pubes. Extirpation of the inguinal glands should also be made in cases where these can be felt. The chain of glands implicated, which are found in these cases, are those of the horizontal and vertical sets.

#### *DIPHTHERIA ANTITOXIN AS AN IMMUNIZING AGENT.*

W. M. DONALD writes in the *New York Medical Journal* of May 21, 1898, on this important subject. He is a firm believer in the immunizing power of antitoxin for at least several weeks following its use; but since a large amount of skepticism is rampant among the profession with regard to this power, and since a number of the better men are questioning it, he feels it necessary to give a reason for the faith that is in him. As such, then, and as a contribution to statistical facts upon this moot point, the following records are presented:

On April 2, 1896, a case of laryngeal diphtheria was discovered at the Detroit Protestant Orphan Asylum. During the next seven days, and despite the most rigid isolation and watchfulness, seven new cases developed. Immunizing doses of antitoxin (two hundred and fifty units of Parke, Davis & Co.'s antidiphtheritic serum) were then administered to the remaining eighty-seven children, with the result of practically stamping out the disease at once. Ten days afterwards, it is true, one case of pharyngeal diphtheria developed, but the other eighty-six cases remained immune.

During January, 1897, a similar outbreak occurred during the attendance of Dr. Douglas. Before it could be controlled five cases of laryngeal diphtheria had developed, two of which proved fatal.

The selective preference of the germ for the larynx in these cases, as well as the sudden outbreak of the poison (all the cases developing within three days), are matters of interest.

At this time antitoxin in doses of five hundred units was administered to seventy-one children, and in doses of two hundred and

fifty units to nine—the latter being the very young, from two to five years of age. The result in this series was even better than in the preceding one—none of the eighty children developing diphtheria after the injection of antitoxin.

In December of the same year, and during the author's service, another outbreak occurred, two cases being discovered on the 27th and four more on the 29th. On the 31st, assisted by his friend, Dr. E. M. Houghton, he immunized seventy-nine children—twenty-five of the younger children with three hundred units and fifty-four of the older with five hundred units of antitoxin—with the result that four days afterward one child who had received the larger dose, a girl of seven years of age, showed well marked faucial diphtheria; the other seventy-eight children remained well.

Out of the two hundred and forty-six children immunized during these three periods, four developed urticaria of moderate severity and three a slight general erythema. These untoward symptoms passed away in about twenty-four to forty-eight hours, giving no further trouble.

In one case on the last date, December 31, 1897, a hypodermic needle of small size was broken in the buttock and could not be recovered. At this writing, almost five months afterward, no symptoms referable to this foreign body, reluctantly allowed to remain in the tissues, have been manifested. The child is under observation and will be watched closely for further report. After each series of immunizations a number of cases of suspicious sore throat developed, with whitish exudates upon the tonsils, but bacteriological examination revealed only cocci, and no Loeffler germs present in any case.

The writer calls attention to the fact that none of these series of immunizations were conducted immediately upon the appearance of a single case of diphtheria, which might have been considered a sporadic waif, and from which no further cases might have arisen; but that on each occasion several days were allowed to elapse after the first manifestation of the disease. During this time the most rigid system of inspection was instituted—every throat in the institution being examined each morning—and every other precaution taken to prevent the spreading of the disease. Despite these measures the disease spread in each of the three outbreaks reported, and refused to be controlled

until the immunizing doses of antitoxin were administered. After that period, as reference to the above reports will show, the disease was controlled without trouble.

The author also calls attention to the varying dose of the antitoxin employed—two hundred and fifty, three hundred, and five hundred units. This was in the nature of an experiment to determine, if possible, the best immunizing dose.

It will be observed that practically as good results were obtained from the smallest dose as from the largest; one case developing after the use of two hundred and fifty units, and one after five hundred units.

We have thus a percentage of failures of only four-fifths of one per cent. in the whole number reported; certainly a most gratifying showing.

---

#### *THE PRESENT STATUS OF HYSTERECTOMY AFTER THE MENOPAUSE.*

J. T. JOHNSON contributes to the *National Medical Review* for May, 1898, a paper on this gynecological topic. He believes that the present status of hysterectomy after the menopause is just about the same as the status of hysterectomy before the menopause.

Since accumulated experience has shown that the "change of life" has very little if any influence in arresting the growth of uterine fibromata in a large number of cases, we cannot count with any degree of certainty upon its favorable influence in any given case. For this reason we cannot now truthfully say to a patient seeking our advice on account of a troublesome fibroid that, as she is nearing the average age for the cessation of her menstrual periods, her tumor will soon cease to annoy her, and will disappear altogether when the change of life is fully established. Indeed, many examples of their rapid increased growth have occurred in the writer's limited experience when the patient had passed the thirty years of menstrual life allotted to the average normal woman.

Uterine fibromata prevent the occurrence of the menopause at the usual age of forty-five to forty-seven, and keep up the monthly periods as well as prove a fruitful cause of intermediate hemorrhages, at a time in the woman's life when she is by nature least able to stand such losses of blood.

Not only does menstruation continue in fibroid cases until the woman is between fifty and fifty-five years of age, on account

of the irritation and congestion caused by its unnatural and offensive presence, but the tumor too frequently takes on an increased growth, becoming larger and more troublesome than before the menopause occurred.

It is quite possible in these cases that the popular idea that the menstrual blood, instead of escaping as it formerly did, now goes to feed the tumor has some foundation in fact. One of the strongest indications for hysterectomy after the menopause is the tendency of the tumor to undergo some form of degeneration which of itself may prove fatal to the long-suffering patient.

The writer has operated on two women with large fibroids, who were both over sixty years of age when the hysterectomy was done, on account of the calcareous degeneration of the tumor. After removal they could not be cut open with a knife or chisel they were so hard, and were only finally opened up with a saw.

Sarcomatous, carcinomatous and cystic degenerations occur, and they also break down by the formation of internal abscesses.

The writer recently presented a 21-pound fibroid tumor to the Medical Society of the District of Columbia, which he removed from a lady fifty-seven years of age, and which contained several pints of bloody pus. The Microscopical Committee of the Society reported that the specimen had undergone a sarcomatous degeneration. While the patient made a good recovery, there can be no doubt that if hysterectomy had been delayed much longer she would certainly have lost her life. It is no uncommon thing in reading the accounts of hysterectomies in the medical journals to notice that the age of the patient was stated to be over fifty. Indeed, Dr. Baer, of Philadelphia, the distinguished originator of "Baer's operation," some time ago remarked: "A large proportion of my hysterectomies were upon women who had passed the menopause." Several papers have recently been published upon this subject, notably one by a member of the District of Columbia Medical Society, and another by Dr. Kelly, of Baltimore.

The age of the patient is no bar to hysterectomy. If a woman has a fibroid tumor threatening her life, or seriously menacing her health by hemorrhage, pressure, degeneration, obstruction of the bowels, peritoneal dropsy, or what not, it should come out no matter whether she is thirty or sixty years of age. Hysterectomy should be done in any and all cases for actual or prospective symp-

toms without reference to age or whether the menopause has or has not occurred. The mere presence of a uterine fibroid which produces no symptoms is not a sufficient indication at any age for so radical an operation as hysterectomy, and, *per contra*, dangerous and threatening symptoms on account of malignant disease or a fibroid tumor of the uterus should be met by the complete removal of the growth, even if the entire uterus were involved in the ablation, notwithstanding the fact that the menopause has occurred.

The mortality of this operation, when uncomplicated by malignancy, in good hands and in favorable environments, should not be more than five per cent. The fatal cases are mostly in that class where delay has resulted in the formation of dangerous adhesions, exhausting complications, and death-producing degenerations.

While a certain number of fibroid tumors are favorably affected by the menopause, those which remain unaffected by the change of life are more liable to take on an increased growth, or as stated above, to undergo one of the forms of degeneration already referred to.

The present status of hysterectomy after the menopause is that it should be resorted to whenever the usually accepted symptoms present themselves which gynecologists the world over acknowledge to be of sufficient gravity to require that operation in any other period of life. These indications being present, the operation is less dangerous than the continuance of the symptoms. Ovariectomy is a very successful operation in old women; there seems to be no reason why hysterectomy should not be equally successful.

#### TREATMENT OF DYSMENORRHEA.

KEITH in the *British Gynecological Journal* tells us that uterine dysmenorrhea is caused by a malformation of the uterus, due to want of proper development. To this is added the thickening of the mucous membrane, along with congestion at the time of the menstrual flow.

It is the bend, plus the thickening of the mucous membrane and congestion, which is the cause of the pain; consequently treatment must be directed either to straightening the bend or reducing the circulation.

The usual history is that the patient has suffered from pain every month since she began to menstruate, the pain commencing with the onset of the flow and abating when the flow is fully established.

In old standing cases there will be leucorrhea, and perhaps some menorrhagia.

If married, the patient will never have been pregnant.

On examination, an ante flexion of the uterus is almost certain to be found. If, however, the dysmenorrhea did not commence until after puberty, in addition to the bend something will be found to account for it. If unrelieved, secondary symptoms arise, due to the pelvic congestion, leading in some cases to disease of the ovaries.

The treatment of this form of dysmenorrhea may be divided into two classes: (1) That directed to reducing the amount of pelvic and uterine congestion; this may be subdivided into (a) general and (b) local. (2) That directed to lessening the amount of the flexion or removing it altogether.

General treatment should be thoroughly tried first, because many may be cured or much relieved in this way. The girl should be kept warm and her general health attended to. Plenty of fresh air should be indulged in, with moderate outdoor exercise. As soon as the period appears the girl must be kept rigidly to bed, and not allowed to get up until the pain has entirely gone. A large poultice should be kept over the abdomen, and for medicine a brisk saline aperient at the commencement, followed by a mild diaphoretic. Sedatives should be avoided as a rule. The stem pessary has had its day; it is unscientific, seldom cures, and may do harm.

There are two other means at our disposal, namely, dilatation by tents or the rapid forcible method, and Simpson's lateral and Sims' posterior division of the cervix. The object of both operations is to enlarge the uterine canal. To keep it open it is necessary to maintain a glass plug in the canal until the wounds have thoroughly healed by granulation, and then to pass a bougie occasionally. The result of this irritation is that the cervix is apt to become hard, and symptoms may arise of as much importance as those the operation was intended to cure. As compared with dilatation these operations have no advantage.

Still another method is Dudley's modification of Sims' operation of backward division. The object aimed at is the straightening of the uterine canal and the healing of the cut surfaces by first intention, so that there will be no hard tissue or possibility of the old bend returning. The most essential part of the operation is the accurate stitching to-

gether of each half of the wound made when the cervix is divided. All the cases in which the author has used this operation have been cured, or have been improved.

Where operation is refused the constant current, after Apostoli's method, will give relief, acting in part at least by reducing the pelvic congestion.—*Medical Chronicle*, March, 1898.

#### THE SURGERY OF THE PREPUCE AND MEATUS.

B. H. DAGGETT, of Buffalo, N. Y., writes on this topic in the *Medical Record* of May 7, 1898. He suggests a new procedure for circumcision which consists of a modified combination of the dorsal and inferior incisions. The dorsal cut is in the central line, extending from the anfractus to within about one-third of an inch of the preputial border. The line of the proposed incision having been marked, a puncture is made at the distal end with a sharp point of the bistoury, and a loop of ligature is passed through this cut, for the purpose of drawing the prepuce tense and holding these mobile and lax structures in proper place for incision. The probe point of thin, long-bladed scissors is now introduced into the puncture, and the entire cut through all the tissues is made with one movement, so that the incision shall be straight, uniform, and inclusive. The inferior incision is made from the preputial margin directly backward for a little more than one-third of an inch, or sufficient to overlap the dorsal incision. These cuts will sever all the constricting tissues of the foreskin. The lower incision is stitched with a fine needle and ligature, so as to unite only the inner membrane and the integument, thus making a thin finished border for the enlarged preputial opening. The foreskin is then drawn back behind the corona of the glans, and these incisions will be transverse instead of longitudinal. The dorsal opening is united by fine sutures in this transverse position, and the edges of integument only are to be stitched together. The prepuce is to be held in this position by the dressings, which are not to be removed for four days, unless there are surgical indications for interference. The writer directs that the surgeon shall brush over the exposed portion of the dressings with Friar's balsam to prevent absorption, and leave the apex of the glans free; then to pack with absorbent cotton, and apply the T-bandage. If the parts become dry and painful, apply properly medicated vaselin or moist

gauze, without disturbing the first dressing. After about four days the healing will be complete or well advanced, when the entire dressing may be removed, freeing the foreskin so that it may be drawn down upon the glans. This operation shortens and widens the prepuce; it sacrifices no tissue; it neither mutilates nor deforms; it reconstructs and creates a cosmetic esthetic covering and protection for the sensitive glans. "The Tysonian brood" is also preserved in both structure and function.

There is no single operative procedure applicable to all of the varying pathological conditions of the prepuce. The surgeon must choose his method with his patient before him. The surgery of the prepuce will test the mechanical skill and judgment of the operator—it is not a trivial matter.

#### THE MANAGEMENT OF PATIENTS BEFORE AND AFTER LAPAROTOMY.

WIGGIN concludes a paper with this title in *The Lancet* of April 30, 1898, by calling attention to the points which he thinks of importance, and which, as they are considered minor ones, are often overlooked. They are as follows: (1) The importance, whenever practicable, of prolonged preparatory treatment of patients about to undergo an abdominal operation. (2) The importance of the administration of cathartics in the early part of this period, followed by large enemas for the purpose of cleansing the intestinal tract. (3) The importance of keeping a record of the body temperature, respirations, and pulse-rate for several days in advance of the operation, and of making a final examination of the urine. (4) The necessity, in the female, of arranging to have the operation performed a few days after the menstrual period, and the cleansing of the vagina even when it is intended that the operation shall be by the abdominal route only. (5) The administration of a small quantity of peptonized food (one ounce) containing stimulants two hours before giving the anesthetic, for the purpose of lessening the tendency to nausea and vomiting after the recovery of consciousness. (6) The necessity of the anesthetic being given by an experienced physician and in the smallest possible quantity. (7) The necessity of protecting the patient's body properly with clothing and blankets during the operation. (8) The advantage of stimulating the patient before the heart has become much exhausted and of

using intravenous saline injections before the radial pulse has become extinct. (9) The leaving in the abdominal cavity after free irrigation of a quantity of hot saline solution for the purpose of stimulating the patient, preventing (?) the formation of intestinal adhesions, and lessening the danger of septic infection of the peritoneum. (10) The necessity of making the patient comfortable by change of position during the first two days of convalescence and by the use of the rectal tube. (11) The necessity for the early administration of food in reasonable quantities and at proper intervals. (12) The necessity of withholding stimulating enemata after operations in which extensive and firm pelvic adhesions have been broken up. (13) The necessity for deliberation as to the wisdom of reopening the peritoneal cavity in a given case of supposed concealed hemorrhage. (14) The importance of washing out the stomach as soon as the diagnosis of intestinal paresis is made and of the persistent use of saline cathartics till the bowels move. (15) The importance of not administering cathartics too early or in too large doses to those convalescing from abdominal operations and who are pursuing a normal course.

#### THE PHYSIOLOGICAL EFFECTS OF OVARIAN JUICE.

FERRÉ and BESTION have studied the effect of a glycerin and water extract of ovary and find it to possess distinct physiological influence in males and females, and they find that males cannot stand the dose well borne by females. If a large dose be given to a male he becomes intoxicated and dies, and a female requires double this dose to produce death. The symptoms shown by the male consist in progressive hypothermia, the production of sloughs at the point of injection, excitement of the genital apparatus with erections and ejaculation of semen, and finally tremors and paralysis. Hematuria may develop. They found tubular nephritis, and in the paralyzed animals congestion of the spinal cords, particularly in the area of the spinal center in the lower dorsal and lumbar region. There were also well advanced lesions in the anterior cornua of the spinal cord. Ferré and Bestion conclude that the juice has a distinct effect and that the partial immunity of females to this effect is due to the fact that they are accustomed to the ovarian juice in that doses similar to those which caused death in the male will do so in

females below puberty who are not accustomed to ovarian activity. They believe that ovarian gland should be cautiously given to women who have passed the climacteric for these reasons.—*La Médecine Moderne*, May 1, 1898.

#### THE CAUSES AND TREATMENT OF HABITUAL CONSTIPATION IN INFANCY.

In the *Archives of Pediatrics* for June, 1898, SOUTHWORTH writes upon this subject. He does not hesitate to assert positively that in his experience it is now exceedingly rare to find a child who is artificially fed whose constipation cannot be remedied by intelligent modification of its diet. In beginning the treatment of a case of habitual constipation, it is usually advisable that the intestinal tract should be gently but thoroughly evacuated in order that the obstruction offered by the accumulated or hardened masses may be eliminated. For this purpose he prefers calomel in divided doses. It may be necessary at first to make daily use of mild laxatives, which facilitate the training of the bowel and assure proper evacuations during a gradual increase of certain elements in the previous diet or the addition of new substances, but the laxatives should then be decreased and withdrawn as soon as practicable.

Too often we yield to the temptation to prescribe drugs rather than study out and remedy the essential cause of the constipation. The former give us quicker results and redound more evidently to the credit of our therapeutic acumen, but in resorting solely to their use under such circumstances we are not doing our duty by our patients or by ourselves. The temporary relief or masking of symptoms by therapeusis, when the etiological morbid condition may be permanently removed by more painstaking application to our problem, approaches dubiously near to charlatanism.

Where a mild action only is necessary, the tablets of rhubarb and soda, of each one and a half grains, made up with oil of peppermint, may be dissolved and given once, twice or three times a day, especially in those cases which depend upon disturbed intestinal function. Where this is not sufficient, the fluid extract of cascara proves one of the most reliable of the well-tested laxatives, infants requiring from one to four minims thrice daily. Preparations of malt with cascara have been highly lauded by undoubted authorities. The fluid preparations of malt,

which have already been mentioned in speaking of the malted foods under the head of dietetic resources, should again be mentioned here with the efficient laxatives. Cod-liver oil, which there are good reasons for classing as a food rather than as a medicine, is peculiarly serviceable in those cases dependent upon poor nutrition, in which the addition of a fat is indicated.

In rather older children, where a more decided action is necessary, other drugs may have to be employed in varying combination to meet definite indications. But it is chiefly where the neglected constipation is of long standing, and where from overdilatation the muscles of the lower bowel have lost their tone, that we need for any length of time to call therapeutics to the assistance of dietetics.

The longer and more carefully the author studies his cases of constipation in infancy, the less he finds that he needs to resort to the use of laxatives for its cure.

For comparatively short periods enemata may be employed with advantage, but they are capable of abuse. For occasional use they may be large, but when used daily the quantity of fluid should be small, the smallest that will stimulate the bowels to contract. Theoretical considerations lead us to the conclusion that cold injections excite more extended peristaltic contractions, and a saline solution is less irritating to mucosa of the bowel than plain water. Glycerin, a teaspoonful in a tablespoonful of water, is a stimulant, has a hygroscopic action, and is one of the best measures at our command.

For cases which habitually require assistance, suppositories of gluten or glycerin are preferable, as they avoid the loss of tone which comes from frequent distention of the bowel by enemata; but the profession has been warned against the use for children of glycerin suppositories which are medicated. Where medicated suppositories are necessary, they should be made with cacao butter, and the proportions of the ingredients controlled by the physician's prescription.

Much of the constipation of later life may undoubtedly be traced to irregular action of the bowels and the neglect of the formation of proper habits in infancy and childhood; so that when we look beyond the present and consider the ultimate results of intestinal torpor in years to come, the regulation of this function becomes imperative in every case, but we should endeavor to accomplish this by removing the cause through the employment of simple and rational dietetic and hygienic

measures, remembering that the abuse of enemata and purgatives, as pointed out by Earle, will eventually diminish the sensibility of the mucous membrane and produce atony of the muscular coats of the intestine.

#### CHRONIC INTESTINAL INDIGESTION IN CHILDREN.

In a recently read paper DESSAU (*Archives of Pediatrics*, June, 1898) discussed this topic. In connection with it he presented a little boy, ten years old, whom he had seen last January, because of nocturnal incontinence of urine and feces. As the boy had been circumcised in infancy, preputial adhesions could not be blamed for the condition in this instance. The boy had a poor appetite, and was very restless at night. He was put upon proper diet and treated for indigestion, with the result that the trouble for which his mother sought advice quickly disappeared.

Dr. Dessau said that the idea that the more food a child eats the better its health seemed to pervade all classes of society, and with most disastrous results. Infants who regurgitate or vomit food do not seem to have intestinal indigestion, because Nature protects them in this way. If starchy food intended for children is not cooked sufficiently to allow of rupturing the starch granules, the starch will not be digested; instead, acetic acid will be formed, and will irritate the alimentary tract. The offspring of gouty patients are very liable to manifest a neurotic constitution, and in these the liability to intestinal indigestion is much greater than in others. In a limited number of cases the seat of trouble might be localized. In young subjects, owing to certain histological peculiarities, the flow of mucus, as a result of irritation, is much greater than in adults. This profuse mucous secretion, so rich in mucin, furnishes an admirable soil for the development of micro-organisms, and of toxins. The large quantity of altered mucus also furnishes a convenient place for the lodgment of intestinal entozoa. Children who have suffered previously from chronic intestinal indigestion, and afterward become the victims of some acute infectious disease, have their symptoms markedly aggravated. The invasion of the mucous membrane in children by the micro-organisms of the acute infectious diseases seems to result in a tendency to hypersecretion of mucus for a long time afterward. The childish victims of chronic intestinal indigestion sleep badly, are

very restless at night, have deep sighing respiration, and sometimes fainting spells during the day. Thirst, a craving for acids, and a general irritability of temper, are also commonly observed. The tongue is moist and glossy, and the papillæ at the side are unusually distinct. Sometimes there are febrile attacks, associated with vomiting, and the passage of mucous stools. More commonly there is constipation, and the stools are pasty and of a light color. A dry, hacking cough is sometimes present in advanced cases, and as it is associated with loss of flesh and a slight febrile movement, it may lead one to suspect pulmonary tuberculosis; but the rise of temperature is not so marked or so permanent as in the latter disease. This point in the diagnosis can be safely and positively decided by the use of tuberculin [of which we disapprove.—ED.].

The reader of the paper went on to say that infants up to four months should not be given more than four ounces at a feeding, and should not be fed more than once every two hours during the day. When old enough to have a mixed diet, the starchy foods should be cooked not less than one hour in order to insure their proper digestion. With older children, milk should form the usual beverage instead of tea or coffee. Meat should be allowed at only one meal in the day. The drinking of pure water between meals should be encouraged. Where there is imperfect digestion of the starchy foods, taka-diastase may be added with benefit. Coffee and tea are to be condemned; also fats and sugar, except in the smallest amounts. A warm wet pack, followed by a cold douche (60°) to the spinal column, is admirable for promoting oxidation of tissue, and elimination of waste matter. Rectal irrigation at 110° F. with the aid of Kemp's tube is a most efficient means of relieving attacks of abdominal pain. Drugs should be used chiefly to relieve pain and flatulence, and for this purpose calomel and bismuth are especially useful. The author's custom is to give calomel, one-twentieth to one-tenth grain, in tablets, every two or three hours for from three to five days at a time, and repeat after a week or ten days. This usually produces a most happy effect. Where there is excessive flatulence or urticaria, bismuth in some form should be administered in doses of five grains three times daily. After dentition, Dr. Dessau prefers the use of a tonic laxative, such as a mixture of cinchona and nux vomica, with senna or cascara sagrada. To this he adds spigelia, not be-

cause it is an excellent anthelmintic, but because in small doses it is a most reliable remedy for correcting that condition of the bowel which is favorable for the breeding of intestinal worms. It arrests the immoderate secretion of mucus and diminishes flatulence. The following formula is recommended:

Fluid extract of spigelia, 2 drachms;  
Fluid extract of senna, 2 drachms (or cascara, 1 drachm);  
Tincture of nux vomica, 1 drachm;  
Compound tincture of cinchona, ¼ ounce;  
Compound syrup of sarsaparilla, ad 2 ounces.

Sig.: One drachm three times a day.

When there is anemia present, and the tongue is not much furred, it is well to alternate the use of spigelia with elixir of the manganate of iron, an elegant and palatable ferruginous preparation. These remedies should be continued, in alternating courses of three weeks, for about three months.

#### THE SURGICAL TREATMENT OF CATARRHAL EROSION OF THE CERVIX IN THE NULLIPAROUS WOMAN.

MUNDÉ tells us in the *American Journal of Obstetrics* for May, 1898, that the speedy and certain cure of chronic endometritis in the nulliparous woman by the sharp curette, whether followed by cauterization of the endometrium with a solution of chloride of zinc or with iodized phenol or not, is generally admitted. And especially rapid and sure is the recovery when the endometritis occurs as the result of a parturient laceration of the cervix, and the curetting is at once followed by the repair of the cervical lesion.

But there are a certain number of cases of endometritis in the nulliparous woman, and even in the virgin, in which mere curetting and cauterization do not suffice to effect a cure. These are the cases in which the catarrhal inflammation of the endometrium has produced a hypertrophy of the glands and papillæ of the mucous lining of the cervical cavity sufficiently powerful to force apart the lips of the virgin os and even to evert the lips to a degree scarcely, if at all, distinguishable from the eversion produced by an actual parturient laceration of the cervix.

This condition must not be mistaken for a congenital fissure of the cervix, which was first described by Fischl, of Prague, in 1883, and later by Penrose in 1896, or with the congenital erosion of the cervix reported by Lepold and Ahlfeld in 1872. Such a congenital fissure of the cervix with erosion the writer saw in his clinic at the College of

Physicians and Surgeons of New York in the winter of 1881-1882, and mentioned the case in his work on "Minor Surgical Gynecology."

In cases where the lips of the external os are not forced apart by the exuberant glands of the cervical mucosa, the glands and papillæ of the vaginal covering of the cervix become disorganized by the chronic congestion, and the epithelium covering the membrane adjoining the os becomes abraded, so that in well marked cases a large part of the sphere of the cervix presents a bright red, raw, ulcerated appearance. This is the condition described in the older books as "granular and cystic degeneration of the cervix," and is not a disease by itself, but simply the result of an old chronic endometritis.

In the author's experience this condition is exceedingly common. He finds in his office case-book as many as seventeen cases in nulliparous married women during the past year and two in virgins. Of course virgins are much less likely to present themselves for examination than married women; but from his observation in past years he is confident that this condition is not at all uncommon even in young virgins. Indeed, he has seen several cases in virgins where the erosion and eversion of the lips of the os was quite bad.

The author does not treat in this article of endometritis and erosions, or hypertrophy of the cervix accompanied by laceration of the cervix, as these conditions occur in the woman who has borne children. He refers exclusively to a similar lesion in the, obstetrically speaking, virgin uterus.

Mere curetting and cauterization will not suffice to cure a pathological condition such as exists in this complaint. One can scrape away the diseased glands and papillæ with the sharp curette, but there will be left a raw surface surrounding the external os which will heal but slowly under the use of caustics, and in its place a cicatrix will remain, with probable contraction of the os. The author has seen this frequently in cases treated by other physicians, especially in former years when the sticks of nitrate of silver were so commonly used to cure erosions of the cervix. The resulting sterility was the cause of his being consulted. It may take weeks and months for such an erosion to heal firmly, and a recurrence of the erosion is not impossible.

Years ago it occurred to Mundé that the excision of the diseased tissue surrounding the external os, the limit of which is shown

by the extent of the erosion on the cervix, and the union of the raw surfaces by suturing, might offer an easy, rapid and certain method of cure. Thus, in a paper on "The Indications for Hystero-trachelorrhaphy, or the Operation for Laceration of the Cervix Uteri," published in the *American Journal of Obstetrics* for January, 1879, there will be found on page 127 the following paragraph: "We are all familiar with the difficulty experienced in curing large granular and follicular erosions of the cervix by caustics. Why not, then, hasten the cure by removing the diseased mucous membrane and uniting the healthy edges by sutures, as is done in Emmet's operation? I am confident much time could thus be saved."

The writer has never specially referred to this suggestion again in print, although he has often practised the method, particularly during the last ten years. But the cases have come under his observation so frequently of late that he has decided to follow the suggestion of Dr. W. H. Lockett, to write up the matter.

The operation is exceedingly simple, and consists merely, after curetting the whole endometrium (the sharp curette in the cervical cavity), in excising with slightly curved sharp scissors or sharp, slender knife the entire diseased tissue to the depth of half an inch in converging directions. The cervical cavity then has the shape of a funnel. The raw surfaces are then united by deep sutures, either silver wire, which he prefers, as it can be allowed to remain as long as desired and assures greater certainty of permanent union, or catgut, which will answer very well in minor cases.

Usually two or three sutures on either side will suffice. As the whole tissue surrounding the external os is excised, it is necessary to prevent the complete closure of the cervical canal and os by passing a thin strip of iodoform gauze through it into the uterine cavity. This is changed every forty-eight hours for a week or ten days, when the patient may be allowed to leave her bed and can be discharged, returning after the next menstrual period to have the sutures removed, if they are wire, or to enable the surgeon to see whether the external os is normal in size and not contracting. It is well to advise such patients to call several times, at intervals of one or two weeks, for the passage of a large (Peaslee's) sound, in order to prevent the contraction which so readily follows plastic operations on the cervix

uteri, especially those performed for congenital stenosis of the os and uterine canal. Even with this after-treatment the operation under anesthesia here described, being safe, short, painless in its after-effects, and, above all, effecting a rapid and sure cure, seems by far preferable to the tedious, uncertain, and quite as expensive routine treatment with curette and caustics.

Of course no cauterization of the endometrium by iodine or any other agent is employed when this plastic operation is performed.

To illustrate the effect of this operation on sterility, the writer mentions that a lady, married a year and sterile, upon whom he operated in this manner last September, wrote him from her home in Texas a month ago that she became pregnant soon after her return home and expected to come to New York to be confined at the usual time.

In the virgin this treatment need not necessarily involve the destruction of the hymen, which has usually been rendered pliant and elastic by the long-persisting catarrhal discharge and permits the introduction of a small Sims speculum, through which the denudation and suturing can be performed without injury to the hymen. But even if that organ were torn the damage would be of small consequence in comparison with the cure of the disease.

---

#### TREATMENT OF EARLY ABORTION BY THE GENERAL PRACTITIONER.

This practical topic is discussed by R. R. SMITH in the *American Journal of Obstetrics* for May, 1898. He emphasizes two points: first, the importance of early intervention, and second, the fact that the operation can be done by the physician under any circumstances. His experience embraces about one hundred cases, treated in all sorts of surroundings, often in houses that were dark and filthy, and usually without an assistant. By far the greater part of these were treated by the curette, and especially is this true of the latter half. We should curette and empty the uterus in all cases of early abortion, except those which are progressing rapidly of themselves, in which there is slight hemorrhage and no sepsis, and the fetus and decidua come away *en masse*. These conditions, according to the writer's experience, are the exception and not the rule, for either there is more or less severe hemorrhage, a rise of temperature, and the case is protracted, or

the contents of the uterus comes away in fragments. When this takes place it is rare for the uterus to empty itself completely for days or weeks, and the patient is constantly submitted to the danger of sepsis or hemorrhage.

The use of tampons should be restricted to those cases where dilatation is slow, unattended by other complications. Such cases require careful watching, frequent change of tampons, and operation if the procedure is not attended by more rapid progress of the case. Tampons should never be used for hemorrhage, curetting being far more satisfactory. He has given up the use of ergot, it tending to retard rather than hasten dilatation.

As to methods of operation, if one can procure a good assistant it will greatly facilitate matters, but this should never deter one from proceeding should none be procurable. The operation can be done without an anesthetic and without causing pain, the greatest gentleness being imperative. One requires a sharp curette, a uterine sound, a fountain syringe, a dilator, a uterine irrigator or soft or semi-elastic catheter. A small pair of placental forceps may be useful in removing large pieces. The patient should be placed across the bed, the feet resting on the edge or, as is often more convenient, on the knees of the operator. A towel wrung dry from a bichloride solution should be placed under the patient. After washing the buttocks, the vulva and the vagina with soap and water and bichloride 1:2000, the hands and instruments being duly prepared, one reaches the cervix and, if possible, removes with the finger (but never with the finger-nail) any large pieces lodging within reach; the other hand on the abdomen will assist this maneuver. With the fingers one may dilate the cervix if necessary, or if that is impossible one may use a Wylie dilator; then with the curette one should proceed to empty the uterus, proceeding by touch alone and using the greatest care not to injure the uterine walls. The finger of the left hand rests during this process on the cervix and guides the curette.

The whole operation, if done with proper care and thoroughness, may take more than half an hour. After one has gone over the walls carefully the uterus should be irrigated. This can usually be most conveniently done with a soft or semi-elastic catheter. It is usually impossible to procure at such a time sterilized water of sufficient coolness, and it has always been the writer's custom to wash

out with mild bichloride solution, 1:4000. He has never had the least trouble from this, but has always been careful to see that none of the solution was retained in the uterus and vagina. He states that he has never dared to depend on the milder antiseptics. The patient is then put to bed and a sterilized pad applied.

The after-treatment consists of bed-rest and antiseptic douches. There may be a few small clots passed within the first twenty-four hours, but, if the work has been well done, nothing further. Hemorrhage means invariably that all has not been removed; the same may be said of sepsis, except in those cases where the trouble has already gone beyond the uterus. Such cases, however, are or should be rare and do not come within the range of this paper.

#### DEATHS UNDER ETHER DURING 1897.

During the year 1897 at least fifteen cases of death whilst under the influence of ether were reported in the public press. As this number is greatly in excess of the previous yearly average mortality, we were led to investigate the individual cases. By the courtesy of the several medical attendants we obtained full details of certain cases, and had hoped to be able by sifting the particulars to arrive at some explanation of such a sudden increase in mortality. The several factors of each case, however, proved so various that no trustworthy conclusion could be arrived at. We therefore give the following brief summary of the facts in the hope that they may be useful. The details of ten of the following cases were furnished direct to us; of the remaining five we have no further information than that given at the several coroners' inquests:

Case 1 was of intestinal obstruction, the result of malignant disease. The patient, a man aged fifty-three, was rather collapsed before the administration of the anesthetic, which was given by a Clover's inhaler. He took the anesthetic well, but vomited while manipulation of the intestines was in progress. There was no preliminary retching, and a large amount of vomit entering the trachea, the patient was suffocated. This case emphasizes the necessity of emptying the stomach before operating on collapsed and debilitated subjects.

Case 2 was that of a woman aged thirty-nine, suffering from ruptured tubal gestation, and in a moribund condition.

The details of Cases 3 and 4 will be found respectively in the *Sussex Daily News* of June 7, 1897, and the *South London Mail* of April 16, 1897.

Case 5 died under chloroform, and Case 6 will be found in full in the *British Medical Journal* of January 8, 1898.

Case 7 was that of a female aged twelve. The operation was for the removal of a large suppurating multilocular cyst of the broad ligament weighing about eight pounds. Previous to the operation the patient was in fairly good condition, but had had a more or less elevated temperature for three weeks. The operation lasted thirty minutes, and about five ounces of ether, which was preceded by gas, were used. During the administration the pulse became more and more weak, the pupils kept contracted, and the breathing became somewhat shallow. The patient having been put into bed and hot bottles, etc., applied, the pulse greatly improved, but the pupils remained contracted, dilating only at the moment of death.

Case 8 was reported in the *Echo* of October 8, 1897.

Case 9, a woman aged thirty-nine, was submitted to an operation for the removal of a retained placenta after abortion. The condition previous to operation was very bad, temperature 104° and pulse 120. Ether alone was administered by a Rumboll-Birch gas and ether inhaler, and an anesthesia had been attained and preliminary irrigation performed, when the pulse ceased to be felt and respiration stopped. From two to four drachms of ether were used.

Case 10 was one of abdominal section; six ounces of ether were given through a Clover's inhaler.

Case 11 is reported in the *Western Daily Press* of September 15, 1897.

Case 12 was an operation for relief of strangulated femoral hernia in a man aged thirty-seven. Previous to the operation there was profuse stercoraceous vomiting. Six drachms of ether were administered from a Clover's inhaler. The patient took the anesthetic well at first except for some struggling, but while passing into the stage of complete anesthesia, some vomit was observed to come up into the mouth without straining, and respiration ceased entirely from that moment.

The operation on Case 13, a woman aged sixty, was for removal of the appendages, together with supravaginal hysterectomy. About six ounces of ether were given, pre-

ceded by gas. Previous to administration the patient was in an apparently good condition and the heart's action was good. At first there was a good deal of cyanosis, but after this the patient took the anesthetic well till about half an hour before the close of the operation, when the pulse became feeble and the respiration shallow. At the post-mortem advanced fatty degeneration of the heart was found.

Case 14 was reported in the *Sussex Daily News* of December 14, 1897.

Case 15 was an attempted hysterectomy as a last resource in a case of protracted hemorrhage in a woman of forty-four.—*British Medical Journal*, May 21, 1898.

#### HYDROGEN PEROXIDE AND SPONTANEOUS COMBUSTION.

LAWALL tells us in the *American Journal of Pharmacy* for June, 1898, that the danger of explosion of hydrogen peroxide, when kept in tightly stoppered bottles, has long been recognized as a serious drawback to the purchase of any considerable quantity at one time. The deterioration or decomposition which, in the most favorable instances, takes place to some extent after several weeks' standing in the bottled condition is accompanied by liberation of oxygen, which (if the bottle be tightly stoppered) accumulates until the pressure is great enough to force out the stopper or burst the bottle, the latter circumstance occasionally being attended by considerable damage to objects in the immediate vicinity.

Although a working process was included for the preparation of hydrogen peroxide in the 1890 Pharmacopœia, at the time of its admission, few pharmacists attempt to make it themselves, and its manufacture is confined to a limited number of firms who make it on a very large scale. As transportation is very detrimental to it, and considering the large amount of it that is handled yearly, the small number of explosions reported is to be wondered at. Probably this may be largely accounted for by the fact that it is usually the custom of the manufacturer to replace bottles broken spontaneously, and it has necessarily made him very cautious regarding the condition of the bottles and the acidity and volume of strength of the preparation when it leaves his hands.

Quite recently, however, the writer's attention was attracted to a new property of this article, which property, it is believed, has

never been recorded. It was the phenomenon of spontaneous combustion, caused by hydrogen peroxide under certain conditions. The property was investigated further, and experiments verified the conclusion that, under certain favorable conditions, hydrogen peroxide is capable of causing spontaneous combustion. The circumstances attending it were as follows:

The writer and his assistant went botanizing in New Jersey. Neither *Rhus toxicodendron* nor *Rhus venenata* were yet in leaf nor flower, although many of the plants were observed and avoided on general principles. The next day the assistant discovered that his right wrist was affected by rhus poisoning, and a course of treatment was begun, using peroxide of hydrogen, which seemed to act very favorably upon the eruption. A cheese-cloth bandage was wrapped about the wrist and kept saturated with peroxide by pouring on a small quantity occasionally. The treatment was discontinued in the evening and the bandage removed before retiring. On the second day of the treatment a rush of work interfered with the previous practise of keeping the bandage constantly moistened, and after several applications during the earlier part of the morning, the matter was entirely forgotten. Several hours later an odor of burning clothes and severe pain in the wrist directed the patient's attention to the fact that the bandage was smoldering and was already charred black in many places. Before it could be removed it had caused several burns on the wrist, which required weeks to heal and which will show scars for several years.

The experiment was afterward repeated by saturating the same material (cheese-cloth) with peroxide of hydrogen and exposing it to the heat of a drying oven, meanwhile observing the temperature and action of the peroxide. Charring took place in all cases, but in no case was it produced at blood heat, the lowest temperature at which the action was observed being 65° C.

The conditions produced by wrapping a bandage in the manner described may lower the temperature of combustion somewhat, but as no one cared to submit to experiment in that direction, the occurrence is given as it was noted, without verification.

The probable cause of the phenomenon is the presence of a slight amount of free sulphuric acid, which is allowed by the U. S. P. for the purpose of preserving the solution. When the experiment was tried with the

hydrogen peroxide which had previously been neutralized, little or no charring effect was produced on the material used, while a one-per-cent. solution of sulphuric acid produced charring to a greater extent than the peroxide in the first instance.

---

*WHAT IS THE BEST OPERATION FOR  
"ADENOIDS?"*

The diligent reader of rhinological literature can hardly have failed to notice that for the removal of the masses of lymphoid tissue in the naso-pharynx, commonly termed "adenoids," very different operative procedures are advocated. Galvano-cautery, the cold snare, curettement, forceps, each has its supporters. Some operators seldom use an anesthetic, others invariably do. The position of the patient is as various as the operative features, some surgeons preferring the sitting posture, others what might be termed the recumbent semi-prone, and others again to have the vertex dependent, etc.

The use of Gottstein's curette as the main dependence appears to prevail as against the use of cutting forceps, though many operators combine their use. Dependence upon the curette alone appears to be irrational, and in fact has been deceptive in its results by reason of the structure of the lymphoid growths. The lymphoid portions of these are held together and attached to the vault by fibrous and vascular tissue, forming sessile pedicles and septa, a sort of placenta, varying very much in its extent and firmness. Now, when this fibrous tissue prevails and the growth is therefore termed "tough" and fibrous, it is not reasonable to expect that an instrument like Gottstein's forceps, which scrapes rather than cuts the growth, will thoroughly remove it. A small, strong, sharp forefinger-nail, such as is possessed by some surgeons, is eminently superior to Gottstein's instrument, especially in curetting out the narrow recesses on the wall of the space anterior to the Eustachian prominences and at the entrance of the choanæ, yet it is well known that the portions of fibrous pedicle and lymphoid tissue left after its use often lead to a return of the growth. These cannot be thoroughly removed by even a very strong finger-nail, much less by a curette scraping over the surface. Some form of cutting forceps is necessary. Such forceps undoubtedly require more care and skill for their use than the curette, but then, skill, care and deliberation are far more necessary for the proper per-

formance of the operation than is generally supposed.

With many operators "ignorance is bliss;" for, after a hasty operation with the curette, during which the phenomenal hemorrhage encourages them to believe that they have been heroically thorough, they fail to explore the cavity a week or two later, and to discover that close to the choanæ a considerable mass yet blocks the way, and nasal breathing is still obstructed.

Haste in operating is mainly due to the very free hemorrhage and its menace to respiration. Hence, it appears wise to place the patient semi-prone with the head sufficiently dependent, and to proceed quickly, but without haste. This, of course, necessitates complete anesthesia, and sufficiently profound to insure the quietness of the patient, say from five to eight minutes, during which time the finger-nail and curette can be rapidly used, to be followed by the proper cutting forceps guided along the left forefinger, which (surgeon on the right of the patient) hooks forward the soft palate and constantly touches the sharp edge of the vomer.

The only fairly practicable way of telling whether all the vegetations have been removed is by palpation, and this must be carefully done, or otherwise portions will escape detection.

The above observations are in accord with many competent operators, and are believed to be in accordance with those general surgical principles which insure safety and success; whereas the methods pursued by many operators are neither safe nor successful. There appears at present to be too much stress laid upon rapidity of operating and brief anesthesia, and too little upon the difficulties and dangers attendant upon the complete removal of some of these growths.

No matter how complete the operation appears to have been, a careful examination of the naso-pharynx should invariably be made a week or two afterwards.—*The Laryngoscope*, June, 1898.

---

*EXTIRPATION OF THE RECTUM; OR,  
WHAT RECTUMS SHOULD BE  
EXTIRPATED?*

MATTHEWS, of Louisville, in the *Physician and Surgeon* for June, 1898, writes a paper on this topic. He says to answer the question, When shall we operate? it might be said:

1. When a dangerous degree of hemorrhage exists.

2. To prevent total occlusion of the bowel.
3. To alleviate great and distressing pain.
4. To prevent further extension of the disease and effect a cure.

To the first proposition—when a dangerous degree of hemorrhage exists—the writer would affirm that he has never had occasion to operate on this account; not that he has not seen cases that bled profusely, but in such cases the bleeding could be and was controlled without the radical operation. In many instances great hemorrhage, or indeed a small hemorrhage, seldom occurs. If, then, such a dangerous symptom does exist, and cannot be stopped, a radical operation is justifiable.

Second, to prevent total occlusion. If, upon examination, it is discovered that but a small opening exists, and in consequence a distressing line of symptoms present, it is not necessarily a case for extirpation, but rather to relieve the strictured condition. There are procedures much simpler, and certainly much less dangerous, that will accomplish the desired result.

Third, to prevent great and distressing pain. It would depend entirely upon what caused said pain, and if an operation would relieve it. Pain in malignant growths is often *inherent*, caused by the involvement of nerves in pathological tissue, and if this condition exists to a marked degree it will call for the extirpation of the growth rather than a colostomy. If, as many suppose, pain is caused by the friction excited by the passage of the feces, then a colostomy is preferable to extirpation, all things being equal. But the author believes that the distinguished surgeons will attest that in many cases of cancer of the rectum, especially when the growth does not involve the sphincter muscles, pain is not a factor in the case. Under such a condition one would not be justified in extirpating the rectum.

Fourth, to prevent further extension of the disease, and to effect a cure. This last reason appeals more to the surgeon, the writer admits, than all others combined. If such result can be obtained, a surgeon would be very remiss in his duty if he did not resort to the most radical method even to accomplish so good an end. But can this result be obtained, and when? Several methods have been proposed by which the entire rectum can be removed. So that it is no longer a question when we shall operate in order to effect a cure. In the early stage and when all the involved tissue can be removed? Yes;

by all means. But shall we operate after this stage has passed? Just as emphatically the author would answer no. The gynecologist is beginning to stop and count over his recoveries after hysterectomy for cancer. Just what the tables are has not yet been tabulated or reported. How many recoveries from extirpation of the entire rectum for cancer is not definitely settled. We know that a certain percentage die as the result of the operation. Some live one, two, three, or perhaps six years after the operation. But would they not have lived just as long without it? Many do; yet may it not be they lived in greater ease? But did they? Some do not. If for relief of pain only, morphine would have accomplished as much. There can be no doubt that when constitutional symptoms are manifest, when by the infiltrative process neighboring organs and tissues are invaded, extirpation is unjustifiable. The operation, especially by the Kraske method, is both a dangerous and a difficult one. With so little to promise, and so much to go through, is it not better to comfort than endanger the life of your patient?

The treatment of cancer of the rectum by extirpation is not a new one. Lisfrance was the first to recommend it. Others followed, but it soon was abandoned. Since Kraske gave us his plan it has been greatly revived. Would it not have been just as well not to have given it such an impetus?

*How Shall We Operate?*—For the treatment of cancer of the rectum a number of plans have been advocated:

1. Caustics, including the thermocautery.
2. Colostomy.
3. Curettement.
4. Removal by the Kraske operation.
5. Removal by the circular method.
6. Palliation, and by division of the coincident stricture.

The first is not much practised and is of but feeble utility.

The merits of the second (colostomy) have been argued *pro* and *con* by many authors. The writer prefers to be classed as an anticolostomist in the majority of cases of cancer of the rectum.

The third method (curettement) is advocated by Tuttle in an able article. The writer fails to see any advantage it may have over extirpation, and it certainly accomplishes less.

The fourth (the removal by the Kraske plan) is received with much more favor in this country than in Europe. It cannot be gainsaid that it is a difficult piece of surgery

and attended with danger. But the principal reason that the writer opposes it is that by a simple method the whole rectum can be extirpated if deemed advisable.

Fifth (the circular method). Any one after doing extirpation of the rectum by both methods must have been struck by the simplicity of this. If any trouble is encountered by removing the coccyx all the room is obtained that is needed. The sacrum in the writer's opinion should be held sacred. H. O. Walker has improved on the Kraske method by suggesting and practising the use of a large Murphy button to attach the upper and lower edges of the severed intestine.

Sixth (palliation). This can be practised by many soothing local applications and by division of the strictured portions. The author would add also that all pain can be made bearable by the use of opium. The writer has been practising a certain plan for the treatment of strictures of the lower gut, which differs materially from that of others. In the last issue of the *New Orleans Medical and Surgical Journal* Professor Ernest La Place, of Philadelphia, discussed his manner of dealing with strictures of the rectum, namely: "The use of the graduated rectal bougies is the most harmful way of tearing the fibers apart, and of removing the stricture. This is done under ether and can be accomplished in a few minutes. In two or three weeks after the dilatation we find that the gut has retained the new caliber by the operation, or should it have a tendency to contract again, the patient is shown how to use a moderate-sized bougie so as to keep the gut patulous." The writer much prefers to forcibly dilate to full extension by a formidable dilator, and not to use any subsequent dilatation at all. His manner is to forcibly break the stricture, to the fullest extent, then plug to prevent hemorrhage. The frequent use of the bougies accomplishes but little, and the friction extended by the same causes additional deposit, especially in syphilitic or benign strictures.

Matthews concludes: (1) That the Kraske operation for the removal of the rectum is not to be advised; (2) that what is known as the high operation for the removal of cancer of the rectum is seldom justifiable; (3) that the opening of the peritoneal cavity in operating for cancer of the rectum is to be deprecated and should not be regarded as a "light affair;" (4) that the circular is to be preferred over the sacral method in the extirpation of cancer of the rectum; (5) that all

malignant growths within reach of the finger, and that can be circumscribed, should be extirpated; (6) that where a stricture exists threatening total obstruction, and it is not considered advisable to extirpate the growth, either colostomy should be done or the stricture should be forcibly dilated; (7) that forcible and free dilatation of a stricture often accomplishes as much as a colostomy, and is much to be preferred; (8) that it is questionable whether the entire rectum should ever be extirpated for cancer.

---

#### ACUTE GASTRO-ENTERITIS OF CHILDREN.

NICHOLS, of Savannah, Ga., thinks that the treatment of this affection in children consists in the use of a purgative, if the case is seen early—preferably gray powder, rhubarb, or fifty-per-cent. emulsion of castor oil, one drachm every two hours, until eight doses are taken. The purgative is the *sine qua non*. Fast the child for fifteen hours, and then give egg-water brandied, panopeptone with cracked ice, every hour or two. Twice a day the author usually irrigates the colon—that is, night and morning; he uses a large catheter or small rectal tube, using the ball-nozzle syringe (fountain) on account of its bulk of tube and free stream. All are acquainted with the irrigation technique, but gentleness and proper temperature of the water are necessary. Sometimes a gallon is required to insure proper washing. Detach the catheter gently, inch by inch, and withdraw it so as to evacuate all fluid remaining in the pouches. The author uses common salt, one drachm to a quart. The water should not be over 110°, that is extreme; 90° is better for ordinary cases. His experience in cold rectal irrigation is bad, griping and abdominal unrest resulting.

The author has had no experience in stomach-washing; his patients resist all suggestions on that line. After the first day increasing doses of arrowroot with burnt spiced brandy, and the irrigations, coupled with hyoscyamus extract and aconite tincture every two hours, complete the cure in mild cases. Drugs, in the author's hands, have not accomplished the wonders spoken of in books on therapeutics. The bath reduces temperature, and by the mild shock the vasomotor paralysis is removed and the capillary vessels react and dilate. Bathing the face and head with water at 60° promotes still further reaction, and the eye brightens.

In a grave case our common sense and tact is more than taxed.

Feeding with barley water, white of egg and brandy, and a little salt, usually tides us over to the convalescent stage.

This acute gastro-enteritis must sometimes be confounded with acute milk infection, which presents similar symptoms, only in a more rapid and alarming degree; vomiting and purging may lead to fatal termination in twenty-four to thirty-six hours in serious cases. In the treatment the physician should not give a drop of milk, but use the treatment outlined above; wash out the intestine at once, and dissolve tannic acid in the water, one scruple to a quart, as it neutralizes the poison. Sustaining, energetic treatment should be given, with baths, meat broths quite warm, one drachm at a time. On the acidity or alkalinity of the stools Nichols bases his nutrition. Thus, acid, greenish stools call for the proteid elements, animal broth, egg-water, etc.; both must be freshly prepared and given in small quantities. Large, frothy, alkaline stools call for the carbohydrates, flour (three pounds), boiled eight hours, cooled, and after shaving off the gummy outer coating, grating the hard, chalk-like mass to a powder, of which with spiced brandy and hot water a fine pap can be made; arrowroot also answers excellently.

Nichols concludes by telling us to use mother's milk if practicable. If this is impossible then we are to use the best artificial foods without milk. Condensed milk after six months is a "snare and a delusion," and gives no resisting power in disease, for on it children do not grow so strong, muscular, or as rapidly as they should.

#### SCALDS AND BURNS.

The object of this article being to review the newer contributions to our list of remedies, the well known measures employed for minor burns, and which all surgeons well know, will not be described. Suffice it to say that the application of bicarbonate of sodium mixed with enough water to make a thick paste, lead-water and laudanum, equal parts of white of egg and sweet oil and white lead paint—which causes the pain to cease almost instantly—have best stood the test of time. It must be said, however, that many newer agents are more effective, both for minor and major injuries; these it is our purpose to review.

*Picric Acid.*—In superficial burns this

agent has been found useful by so many observers who have employed it in a large number of cases that the adverse reports recorded are not sufficient to warrant its rejection as one of our most active agents. It not only procures rapid resolution, but its analgesic action is marked in the majority of cases when employed properly. In deep burns, however, it may give rise to toxic symptoms, and it should not be employed, in the case of children especially, Walter Latouche, Berger and Tuffier having reported marked cases of poisoning in the latter.

Picric acid is a product of the action of nitric upon carbolic acid. It occurs in the form of fine yellow scales, which are soluble in water and alcohol. It is extensively used as a dye, giving a brilliant yellow color to objects over which it is applied. Owing to this property it stains the hands of the operator unless these be previously smeared with vaselin. Stains may also be removed from the skin by means of alcohol or soap and boric acid. D'Arcy Power, who employed it extensively, used a solution made by dissolving one and a half drachms of picric acid in three ounces of alcohol, which is then diluted with two pints of distilled water, a saturated solution being thus procured. The clothing over the injured part should be gently removed, and the burnt or scalded portion should be cleaned as thoroughly as possible with a piece of absorbent cotton-wool soaked in the lotion. Blisters should be pricked and the serum should be allowed to escape, care being taken not to destroy the epithelial surfaces. Strips of sterilized gauze are then soaked in the solution of picric acid, and are so applied as to cover the whole of the injured surface. A thin layer of absorbent cotton-wool is put over the gauze, and the dressing is kept in place by a light linen bandage. The moist dressing soon dries and it may be left in place, for three or four days. It must then be changed, the gauze being thoroughly moistened with the picric acid solution, for it adheres very closely to the skin. The second dressing is applied in exactly the same manner as the first, and it may be left on for a week.

The great advantages of this method of treatment are: first, that the picric acid seems to deaden the sense of pain; and secondly, that it limits the tendency to suppuration, for it coagulates the albuminous exudations, and healing takes place under a scab consisting of epithelial cells hardened by picric acid. A smooth and

supple cicatrix remains, which is as much superior to the ordinary scar from a burn as our present surgical scar is superior to that obtained by our predecessors, who allowed their wounds to granulate.

According to Miles the advantages of picric acid are: Simplicity, painlessness, asepsis, small amount of discharge, infrequent dressings, astringent action in preventing inflammation, property of promoting the growth of epithelium, rapid separations of sloughs, absence of poisoning symptoms, and economy in dressings. Its use should cease, in his opinion, when inflammation has subsided and granulations have formed.

Thompson, of St. Louis, who used it in fifty cases, states that it is advisable to let the shreds of clothing which have been burned into the skin remain until the second dressing. The cloth having been aseptitized by burning, it will do no harm by remaining, while its removal can only be accomplished by stripping away the flesh. The cloth will act as a capillary drain into the skin, and it will promote a permeation of the acid solution into the injured tissue. At a second dressing the thoroughly soaked fibers can be more easily removed. Dressings soaked in a picric acid solution do not adhere as much as other applications.

Picric acid has also been employed advantageously by Thierry, Filleul, Papazoglou, Sila Novitsky, Souter, and others. The author last named simply paints the saturated solution over the burnt surface with a large camel's-hair pencil and leaves the primary dressing, covered with oiled silk and cotton-wool, on for a period of from three days to a week. He says that the solution is used with much success in iron foundries and sugar refineries, a large bowl of it being kept in readiness for emergencies. This procedure could be imitated with advantage on board of war vessels, especially during action.

*Aristol* presents the advantage of being useful in burns of the second and third degrees. It occurs in crystals of light reddish-brown color, is soluble in water, slightly soluble in alcohol, and freely soluble in ether and fats.

In burns of the second and third degrees it has been found strikingly effective where other remedies have failed. Haas states that the pain is most instantly relieved and that healing is rapid. R. Y. McCoy, to illustrate its value in ulcerative processes occurring as a result of burns, cited the case of an engineer

in whom a scald had caused excessive supuration of legs, knees, and soles. An ointment of *aristol* changed the appearance in twenty-four hours, and the healing process continued steadily and with unusual rapidity.

It may be used in the form of powder or mixed with oil or vaselin. The surface should be disinfected with a boric acid solution, and after opening the vesicles *aristol* is applied and the whole is covered with sterilized cotton-wool, gutta-percha paper, and a bandage. The application of *aristol* powder directly to the wound at the beginning hinders the dressing from soaking up the secretion; when the latter is diminished, however, *aristol* may be applied either alone or in a ten-per-cent. ointment with olive oil, vaselin, and lanolin.

Walton, of Ghent, has used the following ointment in the treatment of burns:

R. *Aristol*, 1 part;  
Sterilized olive oil, 2 parts;  
Vaselin, 8 parts.

M.

Around the edges of the burns, after the ointment is spread, he dusts the *aristol* in powder form. In burns of small extent he employs the powder form only. Cleanliness must be thorough whenever the dressing is changed. One of the great advantages of *aristol* is its freedom from poisonous effects. There is some smarting at first, but it soon passes off.

Cookman states that *aristol* may be used in all varieties of burns, from a simple erythema of the skin to a complete charring and destruction of the tissues. In the superficial form it is best used as a powder, while in the deeper burns the following ointment is to be preferred: *Aristol*, 1 part; olive oil, 2 parts; dissolve and add vaselin, 8 parts. He considers the strict asepsis of the wound, however, as the first essential to success. After pricking all the blebs and permitting the serum to exude, the burn should be well irrigated with a weak solution of boric or carbolic acid, and its surroundings scrubbed with soap and water. Then with sterilized absorbent cotton the surface should be gently dried, and the *aristol* applied, either as a powder or an ointment. If the latter is used the wounded edges are first dusted with the powder, and then sterilized gauze on which the ointment has been thickly spread is applied. The dressing is completed with another layer of gauze, absorbent cotton, and a bandage. After three days this should be removed, the wound and adjacent parts aseptitized as

before, and the same dressing reapplied. By careful treatment in this manner very extensive burns will rapidly cicatrize.

*Ichthyol* is also efficacious in treatment of burns of the first and second degrees. Leistikow found that it allayed the pain at once. Slight superficial burns heal rapidly. In burns of the second degree with the formation of bullæ, even when extensive areas are involved, the remedy also acts favorably. It is used dry, diluted with zinc oxide or bismuth, the powder being spread evenly over the surface; in ointment (ten to thirty per cent.); or as a combination of these two methods. The powder is the most satisfactory form in extensive burns of the first degree, and should be plentifully applied. In extensive burns of the second degree the soft paste is preferable.

The zinc oxide powder may be combined as follows:

- ℞ Ichthyol, 1 to 2 parts;  
Zinc oxide, 20 parts;  
Carbonate of magnesia, 10 parts.

M.

While the paste is mixed as follows:

- ℞ Carbonate of lime, 10 parts;  
Zinc oxide, 5 parts;  
Oil, 10 parts;  
Lime-water, 10 parts;  
Ichthyol, 1 to 3 parts.

M.

*Europhen* contains about twenty-eight per cent. of iodine, which it yields on exposure to moisture. It is similar in action to iodoform, but has the advantage of having a less disagreeable odor. Again, it is less poisonous, does not become aggregated in masses, or "cake," and is much lighter. It is, therefore, a valuable agent in burns. It may be employed in the form of powder; but a dressing consisting of three parts of europphen and seven parts of olive oil is to be preferred. Nolda, who has used it considerably, employs the following:

- ℞ Europphen, 1 part;  
Vaselin,  
Lanolin, of each 10 parts.

M.

This he applies two or three times a day to burns limited to rubefaction or vesication. As it only becomes active in the presence of moisture, its beneficial effect in the presence of secreting surfaces is obvious.

*Thiol* has been found useful for all degrees of burns. According to Bidder, it allays pain very rapidly and arrests cutaneous hyperemia. In this manner it tends to prevent ulceration and scars. Giraudon has found it

especially valuable in burns of the second degree, and he also observed that suppuration and cicatrices were avoided even after burns of the third and fourth degrees.

The parts are first washed with a weak antiseptic solution, and the cuticle that may be hanging loose from ruptured blisters is removed, taking care to leave intact those that have not been opened. After dusting the burn with boric acid, the entire surface of the burned region and the skin around it are painted with a solution of equal parts of thiol and pure water. A layer of greased cotton is then laid on the burn, and kept in place with a loose bandage.

*Chloral Hydrate*.—The antiseptic and sedative properties of chloral hydrate make the application of a 5- to 30-grain-to-the-ounce solution quite useful in superficial burns.

*Nitrate of Potassium*.—Nitrate of potassium has been found to be useful in all kinds of burns by Poggi, and may be employed to great advantage when the other agents described cannot be had. It acts mainly as a refrigerant by causing notable lowering of the temperature of the liquid used as a solvent.

If a burned hand or foot is plunged into a basin of water in which a few spoonfuls of the nitrate have been placed, the pain ceases rapidly; if the water becomes slightly heated, the pain returns, but it is allayed as soon as a fresh quantity of the salt is added. This bath, which is prolonged from two to three hours, may bring about the final disappearance of the pain and even prevent the production of blisters. The application of the compresses also exercises the same influence. By this means the pain is allayed and cicatrization takes place without delay.

*Calcined Magnesia*.—M. Vergely obtained favorable results with this salt in burns of the first and second degrees. The affected parts are covered with a thick layer of paste, which is prepared by mixing the calcined magnesia with a certain quantity of water. This paste is allowed to dry on the skin, and when it becomes detached and falls off, it is replaced by a fresh application. Very soon after the paste is applied the pain ceases, and under the protective covering formed by the magnesia the wounds recover without leaving the cutaneous pigmentation which is often observed to follow burns that have been allowed to remain exposed to the air.

*Turpentine*.—H. L. McInnis states that spirit of turpentine applied to a burn of either the first, second or third degree almost

at once relieves the pain, when the burn heals quickly. After wrapping a thin layer of absorbent cotton over the burn the cotton is saturated with common commercial turpentine and covered with bandages. Being volatile, the turpentine evaporates, and it is therefore necessary to keep the cotton moistened with it. When there are large vesicles these are opened on the second or third day. It is best to keep the spirit off the healthy skin, if possible, to avoid the local irritation. Turpentine is also peculiarly useful when the granulations are sluggish. It is a valuable agent for the treatment of burns aboard ship, where turpentine is always on hand.

*White-lead Paint*, referred to early in this article, was extensively used by Prof. S. D. Gross in mild and severe cases, and the results obtained were often remarkable. This excellent remedy is likewise always on hand.

*General Measures.*—Emphasis was laid by Paul Tschmarke, of Magdeburg, upon the great importance of keeping the injured part aseptic; the patient may recover from the shock only to die of blood-poisoning. This is especially to be feared where the side of the face and the chest are extensively burnt. The wound should at once be thoroughly disinfected. He then covers it with sub-nitrate of bismuth, and then with iodoform gauze, kept in place by light bandages. If the bismuth powder is found to irritate the skin and the raw surface, after it has been applied for a few days, he replaces it by boric ointment. Every change of dressing should be made in a bath, in which the previous substances applied are allowed to soak off.—*The Monthly Cyclopædia of Practical Medicine and Universal Medical Journal*, May, 1898.

---

#### OBSERVATIONS ON WHEN TO APPLY HEAT AND COLD IN EYE TREATMENT.

POOLE, of Detroit, considers in the *Journal of the American Medical Association* of May 14, 1898, the therapeutic application of these remedial agents, in some of the diseased conditions we see in our daily treatment of the eye. First, he states as a general proposition that cold causes constriction of the capillaries, thereby checking the amount of secretion and exudation, and in this way acts as a sedative, relieving the pain in the beginning of acute inflammatory conditions.

On the other hand, hot applications are more useful in the later stages, bringing

about a more healthful condition of the tissues involved, and relieving pain by stimulating absorption of the exudate and dilating the capillaries, not only in this way modifying the engorgement, but conveying to the part the life-giving principle for its proper nourishment, and the rapidity with which absorption takes place is greatly increased by the previous application of moist heat. This fact is frequently made use of when using mydriatics. In some cases of iritis, where owing to synechiæ the drug seems to make very little impression on the pupil, if we bathe the eye for eight or ten minutes with water as hot as the patient can bear, we will find absorption take place rapidly and we will get the desired action of the drug.

While moist applications are preferable, there are some cases where dry heat is more applicable and satisfactory, such as scleritis and iritis, where there is apt to be little or no secretion except of tears by reflex irritation.

We will find cold applications more suitable in the following conditions, viz.:

In conjunctival hyperemia, which consists almost exclusively in congestion of the vessels, with slight papillary engorgement, a very moderate increase in the secretion and with no swelling of the membrane, whether it is of traumatic origin or caused by eye-strain. The application of the cold douche or bathing with cold water for a few minutes will be very effectual in bringing about a healthy condition of the membrane, care being exercised in not using water too cold, or the reaction may be too severe.

In acute purulent conjunctivitis, which, as its name indicates, is characterized by a distinctly purulent discharge, thus differing from catarrhal conjunctivitis; for as De Wecker says, "let a catarrh be never so intense it will not give rise to true blennorrhea or purulence." We need vigorous treatment from the beginning, and as an adjunct to other treatment, to assuage the initial swelling and pain, we use ice-cold applications, either by using bits of muslin dipped in iced water, changing them every minute so that the cold may exercise its beneficial influence, or in some cases, if the eye will bear it, small pieces of ice wrapped in muslin may be held on the eye. We need have no dread of untoward results from prolonged use, as the rule, especially in the early stages of this form of disease, is continuous cold to the degree of toleration. These applications are to be continued day and night, ever being watchful of

the cornea to see that it is not becoming involved, in which case the cold applications must cease and be succeeded by hot applications persistently, at least four times an hour for three or four hours, by which time usually the threatened destruction of the cornea will have been stopped, owing to the improved circulation and nutrition.

In ophthalmia neonatorum, cold applied in the same manner will be found just as useful and grateful to the little patient.

Cold applications are also sometimes useful in cases of phlyctenular conjunctivitis when, owing to the distressing photophobia, we cannot get the patient to open the eyelids for the necessary remedies to be used; we drop a few drops of ice-water on the eye, which penetrates between the lids and aids us in gently opening them.

Sometimes in penetrating traumatism of the eye where injury has been done to the iris and the lens, causing plastic iritis and traumatic cataract, ice-cold applications are useful for their germicidal action as well as for overcoming inflammatory reaction.

Poole then goes on to mention a few conditions where hot applications are more suitable than cold.

First, in acute catarrhal conjunctivitis, which while it may present somewhat the same symptoms we found in hyperemia, yet we have here a characteristic stringy, tenacious, flocculent, mucous discharge, with possibly some small masses of pus in it, having a tendency to stick the lashes together. At the very beginning of this condition we frequently find lukewarm applications very comforting and useful, but the error must be avoided of keeping up the treatment too steadily, as is sometimes done by the laity, who frequently make use also of such appliances as potato scrapings, bread and milk poultices, raw oysters, tea leaves, rotten apples, and other disgusting substances, causing edema of the lids and conjunctivæ, intensifying the hyperemia, and finally, in some cases, producing ulceration of the cornea. Such conditions are not rarely met with in the clinics of public institutions.

In edematous conjunctivitis, a condition in which the hyperemia is not marked, where there is little pain and not much discharge, but a considerable effusion of serum beneath the conjunctivæ of both the eye and lids causing a very uncomfortable swelling, bathing with lukewarm water will prove beneficial.

In trachoma, at the beginning of the disease, hot water is not usually well borne. As

soon, however, as vascularity of the cornea arises with threatened ulceration, hot applications are indicated to stay the progress of destruction and assist in its repair. Hot compresses are oftentimes useful in causing the disappearance of the pannus by the inflammatory reaction which they promote.

In the less severe cases of phlyctenular conjunctivitis, lukewarm water will be very comforting and beneficial, helping to overcome the eruptive exudate.

In all forms of keratitis hot applications are to be used, never cold, except possibly in phlyctenular, when ice-cold water may be made use of for the immediate purpose of overcoming the photophobia, as referred to when speaking of phlyctenular conjunctivitis. This is practically the only time we use cold applications in corneal diseases.

The applicability of heat in diseases of the cornea will be well understood if we remember the anatomical structure of this membrane, it being non-vascular and dependent upon the surrounding tissues for nutriment; it follows that inflammatory or diseased conditions necessarily stop the supply of nourishment and death and destruction of the cornea results, as is evidenced by the ulceration. In order, therefore, to hasten the repair of the tissue it is necessary to overcome this stasis, which is accomplished by applying hot water, or sometimes better by dry heat, by folding a napkin and heating it by the fire or with a hot iron.

Phlyctenular keratitis is undoubtedly the form which furnishes the majority of cases of corneal disease, occurring as it does among children who are delicate, ill fed, overfed or scrofulous; and in this class of cases we also see the disastrous results of ignorant interference in treatment by poulticing with the several harmful and repugnant articles mentioned previously, instead of using the simpler and more beneficial hot water compress.

On account of its stimulating properties, the hot compress will be found especially useful in the treatment of ulcers that do not heal readily, hastening the process of repair, while a drop or two of scalding water applied to a fungoid ulcer gives good results.

In suppurative choroiditis we find that hot applications are not appreciated by the patient, but they are very beneficial, especially in mild cases.

Hot applications are often very grateful in muscular asthenopia, allaying the pain, and by stimulating the weaker muscle, removing the troublesome symptoms.

In a general way we may say the rule in all the moderate cases is intermittent use of the local applications of both heat and cold, from ten to thirty minutes at a time, and from three to ten times in the twenty-four hours, the continuous use of the applications being indicated only in the severe forms or in special cases.

#### THE ABUSE OF IODOFORM.

We learn from the *Annals of Surgery* for May, 1898, that Dr. W. G. PORTER recently read a paper in which he sketched the history of the introduction of iodoform into surgical use, and gave extracts from the writings of Mosestig-Moorhof, Moleschott, Miller, Burkhardt, Stillé and Maisch, Le Dentu, Hayes, and others. He called attention to the possibility of toxic effects from its too free use, quoting especially Treves and R. W. Taylor upon that point. As to the manner in which iodoform acts favorably as an application to wounds and granulating surfaces, he gave the views expressed in Hare's work on therapeutics. After this review of the subject he earnestly protested against its routine use to the exclusion of other dressings equally as good and free from its many objections. He said that the general practitioner seemed to think that the only treatment for every furuncle, carbuncle, swelling, ulcer, incision, or wound, was to cover it with iodoform until their patients went around like a walking pestilence, the objects of loathing and disgust to their friends and themselves, and of just opprobrium to their physicians. In hospitals there might be some excuse for its free and practically unlimited use. But in private houses, and particularly in private patients who were going about attending to the affairs of life, there could certainly be no excuse for its use, unless in the rare and altogether exceptional cases in which nothing could possibly take its place. He asked what right any physician had by his treatment to direct the attention of every one to his patient. And yet to-day how few patients who are afflicted with chancroids, herpes, chancre, or almost any other mucous or cutaneous lesion, are spared the infliction of iodoform!

The author gave two examples by way of illustration that had recently come to his attention. The first was a man with a syphilitic ulceration of his face, who had been subjected to the iodoform treatment for a period of four months, absolutely without

relief, the ulcer constantly spreading under the caked and incrustated mass of iodoform. He was the proprietor of a prosperous restaurant in a business part of the city, but the combined odors of the iodoform and the badly treated ulcer drove his customers away, and in less than a year he was bankrupt. The removal of the iodoform and the accumulated filth with proper local and constitutional treatment cured him in three weeks—but his customers had gone never to return. The second case was a man who had been operated on for appendicitis. A fistula resulted—not fecal, but discharging freely a non-odorous albuminous fluid, the only treatment prescribed for which was packing lightly with iodoform gauze. He had his living to make, was able to go about and attend to his business after a long and expensive illness, and yet he was constantly handicapped by the dreadful odor of iodoform, from which he could never escape. The removal of the iodoform gauze and the more thorough drainage by a lead wire healed the fistula in a few weeks.

Dr. Thomas G. Morton said that he did not think the use of iodoform was increasing, but that, on the contrary, it was decreasing. In his ward at the Pennsylvania Hospital there was no patient at present upon whom it was being used. Occasionally, however, iodoform gauze is used as a packing or drain in or about foul cavities. Acetanilid gauze has largely superseded iodoform. A number of druggists who do a large business had told him that the call for iodoform had lessened enormously.

Dr. De Forest Willard said that he used iodoform very little. He would much rather smell fecal pus from the ischio-rectal fossa than iodoform. Thymol diiodide is cheaper and better for fresh wounds. Thymol and acetanilid are sufficient for nearly all cases. He uses iodoform gauze in foul pus cases, but in all clean wounds preferred thoroughly dry sterilized gauze. By using thymol diiodide one is not obliged to pay for the trade name, aristol.

Dr. R. H. Harte agreed that public feeling was opposed to the odor, but he did not think it half as objectionable as many of the perfumes so noticeable on the women who go to the theater. Like every good thing it has been abused, but still it is a valuable drug. All recognize the virtues of mercurial salts, but these also have been abused. He thought iodoform was used nearly as much to-day as ten years ago; certainly during his

half of the term at the Pennsylvania Hospital it was used as much as it ever was. At the Episcopal Hospital it was also used very extensively in the wards by his colleagues. As to the poisonous effects, he had never seen any bad results in his own practise, but he had seen bad effects from it where it was used as a primary dressing in extensive burns. He remembered a series of these cases that were treated by iodoform, and almost without exception poisonous symptoms followed. It was a very valuable therapeutical aid. In tuberculous joints iodoform in glycerin is of great use. It is also very valuable in bone disease. His method of using it in cases where he had removed a large amount of bone was to clean out the cavity thoroughly, wash well with iodoform and glycerin, and pack with iodoform gauze. He thought the results obtained in dealing with bone disease in this way were unquestionably much more satisfactory than with the old methods with carbolized oil. Although iodoform was greatly abused, he considered it a most valuable topical therapeutic agent.

Dr. H. R. Wharton said he did not remember ever having seen a case of iodoform poisoning. As regards poisoning, the conditions where it would be most favorable for its development would be in the modern method of using iodoform emulsion injections. He knew cases where it had been used for a number of weeks for tuberculous joints, but he had seen symptoms of poisoning. He did not use it as much as he formerly did, but he believed it to be a very good remedy in certain cases, as in bone cavities and especially in cases of abscess about the rectum, where no packing could take its place. Used in the same way in operations about the mouth iodoform packing remains sweet longer than any other packing. Experience shows that its use is less safe at the extremes of life.

Dr. George Erety Shoemaker said that he had been unable to find anything which would take the place of iodoform in securing cleanliness in a moist cavity. He had had gauze impregnated with aristol, acetanilid, and other materials, but had found that iodoform gauze would remain sweet twice as many days in a moist cavity as would any other preparation. He thought, therefore, that nothing could take its place when, for example, one is obliged to use a gauze drain after abdominal section for serious types of pelvic abscess or in some cases of appendicitis, or in packing the uterine cavity. The

remarkable duration of the influence of iodoform in keeping a drain sweet was recently illustrated accidentally. He had done a vaginal hysterectomy for pyosalpinx and metritis, and had put in three strips of iodoform gauze for drainage. In removing these one piece, about three yards in length, was left behind, and remained in the abdominal cavity for one month with an end protruding into the vagina. During this time it was thought that the correct number of pieces had been withdrawn. The patient made a nice recovery from operation, and at the end of three weeks was up and about the ward, with a normal temperature. The other piece was found at a routine examination and gave no trouble. On withdrawal it was still yellow in places and did not smell offensive. To his mind there was no other substance which would have kept it sweet under such circumstances.

Dr. W. Joseph Hearn said that the rational use of iodoform was as much indicated today as it ever was. Some people use it for syphilis, but it is perfectly useless. It is useful in chancroids, and nothing can take its place. Its use to the public mind has not the same significance now that it formerly had. People used to think it meant venereal disease whenever it was smelled. When he had an operation in which there was pus and he had to drain he used iodoform; where there was no pus he did not need anything. He rarely used the powder in any surgical work, but the iodoform gauze whenever indicated.

Dr. G. G. Davis said there were two classes of cases in which powders are used antiseptically, one in which the drying element was desired and the other in which antiseptics was to be obtained. In the latter case he did not think there was anything to be compared to iodoform. He had tried various substitutes, but they had not compared in efficacy to iodoform. In the other class of cases he thought it was almost immaterial which of the various powders was used. Iodoform is the most reliable agent we have to stop suppuration when actual contact can be secured. It is the most permanent of all the available drugs, and its action does not cease within a short time of its application; neither is it readily dissolved. The gauze impregnated with it retains its action for a long time, and it is for that reason preferable in many cases to a plain packing. Plain gauze becomes impregnated within a day and contains no material for the prevention of the

putrefactive process. Iodoform gauze seems to stop the secretion and prevent further putrefaction. He had tried one after another of the various remedies, and the only one he really felt that he could rely upon was iodoform. For comfort and drying of wounds and absorptive procedures almost any one of the powders can be used with similar results, but not for antiseptis. As regards poisoning, he had seen two or three cases in old people in which there was a certain amount of constitutional disturbance, and in which the iodoform had been used in connection with operative procedures. In those cases one could not determine exactly the relative responsibility of the operative procedures and the iodoform, but subsequently the patients developed delirium or mental disturbance, which he believed was due to the iodoform. Although those which he had seen had not been of an extremely advanced and serious type, still the mental disturbance in those of advanced age had been so marked as to cause him to be very careful with them.

Dr. Thomas S. K. Morton stated that his present employment of iodoform was limited to its use as a gauze for packing and drainage, especially where dryness and antiseptis were required for prolonged periods; as an injection in emulsion with glycerin for tubercular joints or abscesses; and, occasionally, in the shape of a five-grain suppository in tubercular affections of the rectum. He could not remember having used the substance as a dusting powder for several years. He had seen violent inflammations and vesicular eruptions following its use upon the skin, especially when compressed against the cuticle under a splint in children. He had frequently observed more or less serious constitutional effects from a copious use of the powder in former times, and was ever mindful of the unpleasant possibilities even of iodoform gauze packing. For the latter he has never been able to find a satisfactory substitute, but was inclined to think that iodoform gauze as commonly used was entirely too strong. Dr. Morton for two years has had his gauze prepared of five-per-cent. strength in bandages of various widths and five yards long. These are steamed at 230° F. for half an hour, by which time about from one to two per cent. of the iodoform has been vaporized. Hence his gauze, when introduced into a wound, is not stronger than three or four per cent. of its weight. From this weak gauze he had noticed slight congestive symptoms with rise of temperature,

and mild delirium a few times when large quantities had been inserted. The strips were never lost in wounds, because only one continuous piece of bandage was usually put in. Where dusting powders are required, he has come to rely largely upon bolted acetanilid and compound stearate of zinc, or acetanilid and boric acid. Acetanilid as a gauze has been a failure because of rapid absorption of the drug by the tissues. For chancroids he employs a powerful spray of peroxide of hydrogen, and supplies the patient with a half-ounce of acetanilid with instructions to wash with soap and water twice daily, and afterwards heap as much of the powder upon the sore as it is possible to retain. Then the prepuce is drawn over without dressing. This will cure nine-tenths of all chancroids in a few days. The other tenth will require nitric acid or other destructive agent in addition.

Dr. J. Ewing Mears said that possibly he had given iodoform as thorough a test as any one in its use in the cavity of the mouth. He has used it for many years in wounds of the mouth and in suppurating cavities in a five-per-cent. strength. Never had he seen a well-defined case of iodoform poisoning, but in one or two cases he had seen some effect manifested in the urine by its absorption, but no delirium, or any well-defined symptoms. It may appear very strange, but patients do not complain generally of its use in the mouth. They may complain slightly of it at first. The first dressing which he makes is three days after the operation, and then again in two days, but in cases of copious discharge every day. He had had complaints in private practise, and remembered one case who went away, but finally came back, and he tried it again. It was a case of syphilitic ulcer, and he did not care about letting all his friends know of his condition. He had occasionally used aristol, but by preference he employed iodoform. He had seen nothing in his practise which would compel him to give it up.

---

*ULTIMATE RESULTS OF CASTRATION AS  
A MEANS OF RELIEF FOR OBSTRUCT-  
IVE HYPERTROPHY OF THE  
PROSTATE.*

In June, 1896, the writer published in the *Annals of Surgery* the results of the cases which had been under his personal care in which removal of the testicles or section of the vasa deferentia had been resorted to for

the relief of obstructive hypertrophy of the prostate. He was then able to report eight cases of castration, and three of vasectomy. The amount of relief to the obstructive symptoms which had followed in these cases was very notable, and seemed to justify the conclusion that in these procedures surgery had gained a most valuable resource in dealing with conditions that were not only harassing, painful, and dangerous, but often intractable to any available practicable means of treatment before supported. In the eighteen months that have since elapsed there have been two additional cases in which he has resorted to castration; these he desires now to add to the record:

One case, aged seventy-two years, four months before had been subjected to suprapubic cystotomy and double vasectomy on account of complete prostatic obstruction, not relievable by catheter. At the end of two weeks he found himself able to urinate *per urethram*, after which the suprapubic wound rapidly closed, and by the sixth week was soundly healed, and normal urination seemed restored. This improvement, however, proved to be transient, and marked obstructive symptoms becoming gradually more troublesome again developed, requiring the frequent use of a catheter, which was difficult and painful, until August 12, 1896, when he was subjected to castration. Smooth recovery from the operation followed, with rapid amelioration of his obstructive symptoms, until by the end of four months thereafter he was performing his urinary functions normally, and his general health and strength had become quite restored.

The second case was that of a robust old man, a laborer, aged seventy-five years, who had always enjoyed good health, with the exception of late years of some increase in frequency of urination. Suddenly complete retention developed, which after ten days of systematic catheterization and rest in bed still persisted. The passage of a suitable catheter was not difficult, but the retention remained complete, and rectal examination showed considerable enlargement of the prostate, the right lobe being the larger. The degree of intelligence and the social state of the man were such as to preclude the idea of teaching him to use a catheter in a cleanly way, and any attempt in that line, it was believed, would have been the beginning of infective cystitis. He readily acceded, however, to the suggestion to

have the testes removed. This was accordingly done November 8, 1897. Uncomplicated healing without any mental disturbance followed the operation. No change in his condition of urinary obstruction was noted until the twelfth day thereafter, when he twice during the day voluntarily voided a little urine, but from fifteen to eighteen ounces of residual urine still persisted. This was still his condition one month after operation, but from this time a gradually increasing freedom in voluntary urination was noted, until December 23, six weeks after the castration, he was urinating with apparently normal freedom, and the introduction of a catheter immediately after urination showed that there were but two ounces of residual urine.

The favorable immediate results obtained in these two cases, now first reported, are similar to those experienced in the preceding eight, and are like those met with in a very large number of cases which have been reported by others.

There has been no mortality, or even suggestion of danger of such an event connected with the operation in these cases, although Cabot, writing in 1896 (*Annals of Surgery*, June, 1896), found a mortality of 19.4 per cent. to have attended the cases collected by him from various sources (203 cases, 39 deaths). But, obviously, it is one thing that death followed an operation, and quite another thing that death was due to the operation!

It would, perhaps, be a more just interpretation of the facts to say that in a considerable proportion of the reported cases—about twenty per cent.—the conditions preceding the operation had been such as to entail a speedy fatal result notwithstanding the operation, not denying the fact that probably in some instances the inevitable end had been accelerated by it, for the remark is also a just one that a serious pathological condition, in the course of which a surgical operation is done, is prone to be aggravated by such operation, if by it the condition is not at once greatly relieved. Castration done on a patient moribund with uremia; castration done on a patient profoundly prostrated by sepsis from a suppurating prostate or kidney, or necrotic bladder; castration done on a patient with overdistended bladder with pressure effects upon the kidney; castration done on a patient worn out with the suffering caused by the presence of a calculus in the bladder, will, if unaccompanied by the measures required for the immediate relief of the urgent

conditions, be productive only of harm. It is quite evident that castration should not be resorted to in such cases as these mentioned, until after the pressing emergency has been relieved by the use of appropriate measures and a favorable state has been created for the introduction of a procedure which may gradually, and possibly only after the lapse of weeks, induce a subsidence of the prostatic obstruction. The value of such a course is strikingly illustrated in two cases of his series, in each of which by suprapubic cystotomy free bladder drainage was provided for and maintained for some weeks before resort was had to castration.

Of more importance is the possible effect upon the mind and disposition of the man produced by withdrawing from him the special stimulus furnished to the economy by the glandular products of the testes.

Acute mania, dementia, and gradual loss of vigor, causing the patient after a time to succumb to conditions which before the removal of the testes had been well borne, are the states which have been more especially ranked as fairly frequent sequelæ to the operation. The later history of castrated prostatics is therefore of special interest from this point of view. In the previous report the author gave the details of one case in which a distinct tendency to dementia developed immediately after the operation in a man seventy-two years of age, with an atonied overdilated bladder, dribbling at thirty-seven ounces. At the end of three months, however, by which time the function of urination was being normally performed, his mental condition had greatly improved. His later condition is unknown to the author.

One man, sixty-eight years of age, died of dysentery some months after castration.

One man (the second case reported in this paper) is of too recent date, as an *opéré*, to have any late history. The remaining seven cases the writer has been able to follow, and their condition to day, in brief, is as follows:

CASE I.—Time since castration, three years; present age, seventy-seven; hale, hearty, and active physically and mentally. Still has five ounces of residual urine, which he evacuates with catheter night and morning. Urinates spontaneously every two or three hours.

CASE II.—Time since castration, two and a half years; present age, fifty-eight; a clergyman in charge of an important church; states that his physical vigor and his mental grasp have notably improved since operation. His originally long overdistended bladder, drib-

bling with sixty-four ounces, still halts with ten ounces of residual urine, requiring catheter for its removal.

CASE V.—Another clergyman. Time since castration, two and a quarter years; present age, fifty-four years; still continues to preach with acceptability and to administer the affairs of his parish with prudence. Still has some residual urine and a chronic cystitis, which requires the use of a catheter and daily irrigation of the bladder to keep under control. Reports that urination is now attended with more difficulty and pain than it was during the first year after the removal of the testes.

CASE VI.—Time since castration, two years; present age, sixty-seven years; general health excellent; mental grasp undiminished; still attends actively to the affairs of an important business. His chief annoyance has been the frequent occurrence of uncomfortable flushes of heat similar to those experienced by women at the time of the menopause.

CASE VII.—Time since castration, one and three-quarters years; present age, sixty-four years; in good health, sound mind, and free from all urinary disturbance.

CASE VIII.—Time since castration, one and three-quarters years; present age, seventy-two years; in good health, sound mind, and free from urinary disturbance.

CASE IX.—Time since castration, one and a half years; present age, seventy-four years; is hearty and vigorous; devoted to equestrian exercise; manages with skill a spirited horse.

This completes the record of the writer's personal experience to January 1, 1898. Certainly in these cases the relief from the special sufferings and difficulties incident to obstructive prostatic hypertrophy has been great; in some of the cases it has been complete, the freedom of urination having been restored to the normal point; in others, some obstruction persists, even after the lapse of some years, requiring catheter-help at times, but in a degree very much less than before castration.

This relief has been secured by a procedure that has been free from pain and has been attended with but little, if any, risk to life; the worst blur upon the record is the infliction of a few weeks of childishness upon one patient. The procedure is one that demands no special surgical experience, nor elaborate ménage, nor peculiar or costly instruments for its proper performance. It seems to the writer that it has at least won a

place for serious consideration whenever the problem of the relief of urinary obstruction due to prostatic hypertrophy is presented for discussion.—LEWIS S. PILCHER, in the *Annals of Surgery*, May, 1898.

*A SIMPLE METHOD FOR CONTROLLING HEMORRHAGE DURING DISARTICULATION OF THE HIP.*

LYNN THOMAS, in *The Lancet* of April 23, 1898, says that in emergencies the ideal method for controlling hemorrhage in amputation is undoubtedly that which requires no special instruments in one's operating-bag. Perhaps the majority of the younger surgeons do not realize that the loss of blood is quite insignificant in disarticulation of the hip by the anterior incision because the femoral artery and vein are ligated at the outset of the operation (Treves). The author thinks the amount of blood lost is less than the quantity of blood driven into the body by vertical elevation of the limb for a couple of minutes prior to the operation. In a properly equipped operating-room, surrounded by competent assistants, the surgeon can adopt either a simple or complicated method of arresting the hemorrhage with equal comfort and confidence of success; but in a badly lighted room with incompetent or inefficient assistance in a private house amputation at the hip becomes a very serious and anxious undertaking unless one happens to possess two one-foot skewers and at least two yards of india-rubber tubing in the operating-bag (Wyeth's). In Swain's "Surgical Emergencies" (fifth edition) Davy's lever and Jordan Lloyd's methods are the only two referred to in connection with the arrest of hemorrhage in disarticulation of the hip. The first method is practically obsolete, though extremely ingenious, and very few men are *au fait* with the other method.

During the last twelve months the author has had to disarticulate at the hip on three occasions, once at the infirmary and twice in private practise: (1) For sarcoma of the femur; (2) for osteomyelitis of the femur; and (3) for an injury. On one occasion he used with satisfaction the following method: The common femoral artery and vein were temporarily compressed immediately below Poupert's ligament. At this point the artery is quite superficial and easily felt and is well above the origin of the deep femoral artery. The femoral pulse being felt, he made two stab punctures in the skin, one about an inch outside the pulse and the other about two

inches to its inner side—*i.e.*, immediately below the pubic spine. An aneurism needle with two eyes (Horsley's pattern), which he always carries in his bag, was pushed from one stab puncture well behind the artery and vein to the other stab puncture, and two long, thick silk sutures were carried through in withdrawing the needle; then a pad of Gamgee tissue was rolled up and placed over the artery between the punctures, the two silks were tied separately over the Gamgee tissue, and thus the vessels were efficiently and satisfactorily occluded during the operation. It is advisable to simply tie the first stage only of the surgeon's knot and clamp it with the forceps, and by this means we can easily retie if necessary when letting go after ligating the visible blood-vessels on the face of the stump. The only condition which might embarrass one in adopting this method of controlling hemorrhage in amputation at the hip would be the occurrence of an irreducible femoral hernia. There is a method of controlling the same vessels by means of a large Doyen's broad ligament forceps; only one puncture is made on the outside of the femoral pulse, and one blade is forced through behind the vessels and then the forceps is clamped. This method would be quicker and would take only a few seconds to apply, but it means the acquisition of a special instrument which is not in every operating-bag, whilst the first method requires nothing beyond the essentials of every operating-bag.

The author is not aware that the principle of underrunning the vessels with silk and tying it over them has been applied to the common femoral vessels before, whilst it is a recognized method of treating cirroid aneurism of the scalp. It is hardly necessary to add that after placing the ligatures and pad (in the method he once adopted successfully) it is necessary to elevate the limb to drain it of its blood before tying the knot tightly. If one were amputating at the shoulder-joint single-handed the same method would be found very useful.

*THE SURGERY OF THE KIDNEY.*

HENRY MORRIS in an important article on this topic in *The Lancet* of April 23, 1898, thus summarizes his views:

1. That the aim of the surgical treatment of renal calculus should be to extend the application of nephrolithotomy and thereby restrict the necessity of nephrotomy and nephrectomy.

2. That more frequently than not the failure to find a stone is not in reality a failure of treatment, because there are so many curable morbid conditions which mimic renal calculus and which are discoverable only by exploration.

3. That the theory that a stone in one kidney, whether that kidney is itself painful or not, reflects or transmits pain to the opposite kidney is quite unproven; that it is a dangerous theory, calculated to lead to very erroneous practise, and that the surgical principle with regard to exploratory operations should be that with pain, paroxysmal or continuous, on one side only, the kidney on the painful side should be explored.

4. That nephrectomy for calculous conditions is very rarely called for and should be done only in most exceptional cases. Nephrotomy for calculous pyonephrosis is the proper operation, because of the frequency of double calculous disease. Experience has shown that kidneys from which stones weighing 830 grains and 1300 grains have been removed are functionally sufficient to maintain life during the blocking of the ureter and the suspension of the function of the kidney of the opposite side.

5. That nephrectomy whilst the opposite organ is occupied by calculus is fraught with very great danger to life; whereas nephrectomy after the opposite kidney has been freed from stone will probably be followed by recovery from the operation and possibly by very good health for years afterward.

6. That when renal calculus causes reflected or transferred vesical or ovarian pain, the removal of the calculus will be followed by complete cure of the bladder or ovarian symptoms.

7. That in some cases renal calculous conditions are attended by very remarkable nervous symptoms, sometimes with, sometimes without, high temperature, and that information as to the cause of these symptoms is needed.

8. That unsuspected renal calculi are a source of very real danger to their possessors, and when, whether by accident or by the systematic examination of the urine, we have cause to suspect the presence of a calculus we should recommend its immediate removal regardless of the fact that it is not causing renal or transferred pain.

9. That quiescent calculus is as dangerous to the individual as unsuspected calculus and ought to be removed by operation.

10. That the hitherto accepted teaching that

a renal calculus, if causing only mild symptoms or attacks of renal colic of only recent occurrence, should be treated on the expectant plan ought to be discarded as unsound in theory and dangerous in practise.

11. That the same principle should be applied to renal calculus which has long been the rule in regard to vesical calculus—namely, when suspected it should be searched for, and when known to exist, removed, without waiting in the hope that it may become encysted or spontaneously expelled.

12. That the very low mortality of nephrolithotomy puts this operation upon the same footing for renal calculus as lithotripsy in the most experienced hands for vesical calculus.

---

#### CLINICAL REMARKS ON STRICTURE OF THE URETHRA.

HARRISON in *The Lancet* of April 23, 1898, writes on urethral stricture and thinks that the following classification of strictures is one which may be conveniently used for clinical purposes: First, those amenable to some form of dilatation; second, those found to be unadapted for such treatment and where other measures should be considered; and third, those which may have been regarded as impassable strictures. The author limits his remarks to questions arising under these three headings.

The first class includes by far the greatest number and all strictures in their early stages. When this process of treatment proceeds satisfactorily, as it usually does, the patient is soon able to take the management of his own case after he has been instructed in the use of the appropriate instrument. For whatever is done in the way of treatment by dilatation or otherwise, in the majority of advanced forms of urethral obstruction the patient can seldom hope to entirely dispense with the passing of a bougie. When a person who is suffering from symptoms which may indicate stricture presents himself for the first time, much care is required in exploring his urethra with a catheter or bougie. It is very easy to spoil a stricture and so lose the way through it. Thus future access to the bladder may be rendered rather more than less difficult. On making an examination of this kind the aim should be to ascertain, without causing pain or bleeding, if possible: (1) the presence and position of the obstruction, and (2) the degree of contraction that has been arrived at. It is undesirable to endeavor to pass an instrument into

the bladder without knowing all this beforehand, otherwise we may easily select one too large for the purpose and so in the first attempt do more harm than good. The thinnest end of the wedge must first be inserted, and then the dimensions of the contraction can be readily and accurately gauged.

In view of giving effect to these points the author described fifteen years ago a flexible conical bougie or dilator which, so far as his experience of it goes, has superseded most instruments of this kind and has been the means of considerably reducing the number of what are called impassable strictures. These instruments are used both for locating and measuring all kinds and degrees of urethral stricture. They are about twenty inches long, commencing with a fine probe-ended extremity, which gradually expands in the opposite direction. They are made in different sizes and are rendered extremely flexible when placed in warm water for a few minutes, if necessary, before using them. In this way they will readily coil up within the bladder. He much prefers the French make (Lassère's); he finds them useful, not only for the purpose he has mentioned, but for smoothing out a rough urethra and making the access to a stricture funnel-shaped, so that it may be easily entered by almost any other instrument. The late Mr. Lund, of Manchester, christened them "whips" when the author first showed them and he adopted them, and they have since always gone by this name. Bangs' filiform bougies, made on the same principle of the finest whalebone, are applicable to even more contracted forms of obstruction, such, for instance, as the eccentric pin-hole strictures which are occasionally met with. They may also often be used with advantage as pilots for the "whips." The author can strongly recommend both of these instruments to practitioners who are liable to meet with stricture cases and have not hitherto given them a trial. Either of them will do duty in an emergency in relieving a retention of urine in the absence of a catheter by at once dilating the stricture to almost any extent by a single introduction of the instrument. On its withdrawal the patient is usually able to empty his bladder immediately by his own efforts. He has frequently used them in this way with prompt relief. He thinks they should be more generally known. No force can be exercised by them, otherwise they will double up and the object is defeated.

Passing to the second class of cases, which

includes strictures found on trial to be unadapted for any form of dilatation when for any reason a large amount of scar tissue has been imported into a stricture—as, for instance, in obstructions following wounds and injuries of the urethra—it may be found impossible to sufficiently dilate the contraction which follows. This may proceed from some difficulty in connection with the access or entrance to the stricture, as when damage has been done to the interior of the urethra, from the inherent contractility of the tissue composing the obstruction, or from certain constitutional disturbances following attempts at dilatation even of the gentlest and most gradual kind.

In instances such as these and the like immediate and permanent good to the stricture may be done which will not yield to dilatation alone, and thus prevent the bad effects of back pressure gradually extending to the bladder and kidneys above, by introducing a splice of new material into the contracted portion of the canal, much on the same principle as we should expand a tight garment. For these purposes the author usually selects Maisonneuve's instrument. It consists of a fine pilot and director upon which runs a small triangular knife dulled at the apex. It can thus only divide the contracted portion or portions of the canal, and this it does by a clean linear longitudinal incision corresponding in depth with the size of the blade. As healing takes place, under the use of a bougie a splice or interval of new tissue is introduced between the lips of the incision, and thus the caliber of the canal may be considerably increased in a short time. For forty-eight hours or so before this is done it is well to sterilize the urine with some boric acid taken by the mouth in small doses, or with what he has found still better, boracite. The former sometimes produces indigestion, whilst the latter is both pleasant and reliable. The filiform pilot is then passed through the stricture into the bladder, the fine metal director following it. The urethrotome is next run along the groove into the latter, and the stricture or strictures are divided from before backwards. Care should be taken not to run the blade further than the last point of contraction, so as to avoid touching any fibers of the sphincter. The latter is unnecessary and may cause some bleeding. To make sure that all stricture fibers are severed and a clear interval is provided between the lips of the incision thus made, a short series of Lister's metal bulbous bougies

(10 to 15, English gauge) should be successfully passed before the patient recovers from the anesthetic. The ordinary round-ended bougies are not suitable for this purpose, as they may catch in the lips of the wound. It is a matter of much importance to secure a perfectly smooth, soft scar. All metal instruments for use in connection with a strictured urethra should be bulbous or olive-headed. The bladder is then emptied of any urine it may contain and washed out with a solution of perchloride of mercury (1 in 6000) until the lotion returns quite clear. An ounce or so of the solution is left behind in the bladder, so that the first portion of the urine voluntarily passed is sterilized.

This completes an operation which need not occupy more than a few minutes. Carbolyzed vaselin (three grains to two ounces) is used for the instruments. The author rarely ties a catheter in the bladder unless, as sometimes happens, a chronic stricture has induced an atonic bladder, when a soft-rubber catheter may be retained for forty-eight hours or so; otherwise we may have high temperatures until the viscus is artificially emptied. With these antiseptic precautions there is seldom any marked degree of urinary fever. On the fourth or fifth day after a whip bougie is generally passed, and the patient is instructed in the use of a suitable instrument. For many years Maisonneuve's operation has commended itself to the author on the grounds of its simplicity, its adaptability to the most contracted forms of stricture, and the benign character of the scar tissue which usually results. He has therefore referred to some details to which he has learned to attach considerable importance. The extension of the antiseptic principle to these operations has in all respects greatly benefited them.

Still more rarely there are cases of stricture met with where neither dilatation nor internal urethrotomy will cover the ground the contraction occupies. Instances occur when, by reason of contraction, abscess, and fistula, the perineum and urethral wall become matted together and converted into a hard mass of dense warty-looking tissue which can be only successfully dealt with by some form of perineal section. This, however, though the cases may be comparatively few, is a subject of itself and requires a consideration which cannot be included within the limits of these remarks.

The author passes on to the third division of his classification—patients who present

themselves for treatment on the ground that they are suffering from an impassable stricture. In the author's earlier days he was much impressed by the teaching of Syme, indorsed by Bickersteth, of Liverpool, in his practise, to the effect that such a term as "impassable" could only be used in a somewhat relative sense and was inapplicable unless the canal was structurally or, if he might use the term, hermetically closed, as, for instance, when a urinary fistula coexisted. Syme thus refers to this point: "There is nothing of more consequence in the treatment of stricture than knowledge of the fact that this alleged impermeability has no real existence except in those cases where the urethra has been divided by violence and allowed to cicatrize with obliteration of the passage beyond the opening at the seat of injury. It is obvious, indeed, that if the urine is permitted to pass, no matter in how small a stream, there must be room for the introduction of an instrument, provided it is sufficiently small and properly guided." This is a high ideal to take and to attempt to follow, but it puts into prominence the first principle associated with the treatment of urethral stricture, whatever form it may assume. Though we may fail to attain it, the possibility of doing so in a legitimate and scientific manner should never be lost sight of. If such a conclusion as this could have been arrived at in the time of Syme, how much more so is it within our reach in the present day, after what has been done in improving the construction of all kinds of instruments used for this purpose. Though much patience and tact are required in obtaining access to the bladder through a contracted stricture, failure, he believes, need now but rarely occur. Nor is the attainment of this a matter of indifference relative merely to the adoption of one out of two eligible courses. Experience shows that as there are strictures which need not be cut merely because they may seem in the first instance to be impassable so far as a bougie is concerned, so there are strictures which though passable in this sense are yet found to need cutting. No sufficient answer can be given to the important question that is thus raised until a stricture has been fully explored, and this he believes can be generally done. For an impassable stricture he does not think there can be any better alternative than the one associated with the name of Mr. Wheelhouse, where the contraction is sought for by opening the perineum. It

would, however, not be difficult to find many surgeons largely engaged in operative work who have never availed themselves of this proceeding on the ground that a stricture had resisted all legitimate efforts to enter the bladder along the urethra.

### *LONDON LETTER.*

BY RAYMOND CRAWFORD, M.A., M.D. OXON., M.R.C.P.  
LOND.

The holidays are now close upon us, and the medical year may be said to come to a close with the meeting of the British Medical Association at Edinburgh in the last week of July. In the Section of Therapeutics was an interesting discussion on the treatment of chronic renal disease, which is particularly desirable at this time, when a revolution so to say of the traditional treatment of this disease has been brought about. Dr. Ewart has recently contributed some ingenious suggestions on this subject to the Clinical Society of London. He starts with the assumption that in most cases of tubal nephritis the disease is confined to the epithelium, and represents a condition of inveterate epithelial catarrh that should be treated on these lines. We fancy, however, that if Dr. Ewart were to carefully examine with the microscope any dozen successive kidneys of tubal disease, he would find a much greater constancy of intertubular change than he seems to suppose exists. However, this in itself should not tempt us to neglect the catarrhal factor as has been done in the past, any more than we would neglect bronchitis in a lung where interstitial pneumonia was present. Dr. Ewart regards renal edema as Nature's safeguard against fatal intoxication, and at the same time, if allowed to persist, as Nature's great difficulty and danger. Thus the edema chokes the lymphatic system, disturbs the processes of nutrition, and hinders the recovery of the kidney by blocking its drainage. Ewart suggests that if systematic drainage of the lymphatics can be insured, the kidney may be left very much to itself; in fact, he would have us regard the danger of tubal nephritis as lying in the lymphatic system rather than in the kidney. He would coax the effusion by gravity to the lower limbs, where it can be continuously drained by aseptic scarification, or by Southey's tubes; this he effects by raising the head of the bed.

At the same time the edema of the upper extremities may be relieved by massage, and that of the serous sacs by paracentesis. He claims to satisfy indications of prime importance by this method, such as the constant removal of contaminated fluid, physiological rest to the kidney by opening another channel of excretion, and restoration of circulatory equilibrium. Ewart suggests that in nephritis, as in pneumonia, the inflammatory products are mainly removed by the lymphatics, and that a free lymphatic flow is for this reason a first indication in nephritis. It is difficult to negative this hypothesis, but it is a matter of common observation that a large amount of inflammatory excreta escape in the urine, so long as the lymph channels are blocked. Such a view certainly has a clinical analogy in many cases of pneumonia, in which an extensive consolidation undergoes resolution without any increase in the sputum, while in other cases the whole work seems to be done by expectoration rather than by reabsorption.

Dr. Ewart condemns the orthodox treatment of tubal nephritis: (1) Because instead of relieving edema, the tendency has been to promote its permanence; (2) because it has not supplied physiological rest to the kidney; (3) because the kidney has been provoked to diuresis when its functions were already in abeyance, while diaphoresis and purgation have drained the strength of the patient, rather than his edema; (4) because the diet most suitable to the constitutional condition of the patient has been withheld. Ewart adopts a far more liberal diet than is generally conceded, on the theory that the toxic products are constantly removed by the systematic drainage. We can confirm from experience in several cases that it is possible to keep up continuous drainage by linear scarification for weeks and even months without ill effect, provided full antiseptic precautions are observed throughout. Along with an ordinary mixed diet he allows a moderate amount of tonic wine such as Burgundy or claret for the general well-being of the patient. Again he maintains that with the reestablishment of the lymphatic circulation drugs can be used, such as digitalis, with much greater effect on the heart and kidney, and this is a proposition that every physician will indorse. Ewart suggests that uremia may be relieved by draining dropsical fluid, as it has been relieved by venesection, and with less call on the strength of the patient. Having regard

to the nature of the effused fluid, which has recently been very fully investigated by Bradford, this would seem to be probable, but such a slow method of relief could be of little practical value in any case of acute uræmic manifestations. There is much in Ewart's suggestions that should be carefully weighed in the balance of clinical experience. It would certainly seem reasonable to aim at a more radical treatment of the renal block, on which, apart from the nephritis, much of the albuminuria depends, both for the purpose of restoring the excretory function of the kidney, and therewith also maybe its power to produce an internal secretion of essential value to the economy. We fancy Dr. Ewart's eyes are riveted too closely upon the kidney, and before a verdict could be given on the curative efficiency of his suggested treatment much would have to be said of the heart and of other organs.

Our indefatigable Colonial Secretary has set on foot a scheme for establishing a School of Tropical Medicine in connection with the Seamen's Hospital at the Albert Docks. Now that a large portion of the tropics is included in the Empire it is certainly proper that the medical men of the colonial service should have some facility for the study of tropical diseases, which hitherto has been completely neglected in this country. The Seamen's Hospital has long provided material from all parts of the world, and only some solid scheme is necessary to make it available for students. The school which it is proposed to found in connection with the hospital will have the advantage of Dr. Patrick Manson's knowledge of tropical diseases, and there should be no difficulty in finding adequate lieutenants among the members of the colonial service. The Colonial Office is to supply a portion of the building fund, together with the annual fees of students who propose to enter the colonial service. It is hard to see why the India Office and the Foreign Office on behalf of its protectorates in East and West Africa should not support the scheme, and supply some of the cost of maintenance. Such a school, with a well equipped laboratory and facilities for research, such as are promised, should attract students from other countries than our own.

Dr. Maclellan contributes some notes on alginic acid and some of its compounds as therapeutic agents to the July number of the *Glasgow Medical Journal*. Alginic acid is a new organic acid obtained from algæ. We are not here concerned with the uncombined

acid, for which Maclellan gives the empirical formula  $C_{76}H_{80}N_2O_{22}$ , but rather with the compounds of the acid. The alginates of the alkalies and magnesium are soluble, but those of the alkaline earths and heavy metals are insoluble, though many may be rendered soluble by ammonia. Maclellan suggests that alginates of many of the alkaloids might conveniently be introduced into the list of official remedies. All the alginate salts have the peculiarity that they are but little acted on by pepsin, and may therefore be used when it is desired that they should pass through the stomach unchanged. The paper deals at length with alginate of iron, which is a tasteless, brown, insoluble powder, and contains a very large proportion of iron, viz., 10.92 per cent. It is best administered in the form of powder, and may be given to adults in doses of from ten to fifteen grains thrice daily. Maclellan had thus employed it in several cases of chlorosis, where there were marked symptoms of functional or organic derangement of the stomach, and found it well tolerated, when the stomach rejected other preparations of iron, such as the saccharated carbonate. The alginate seems to be free from the astringent properties of many iron compounds, which tend to produce troublesome constipation, and on the other hand seems to avert this ill consequence by its tonic influence on the intestinal muscle. Maclellan attributes the tolerance of the stomach to this compound to the fact that alginates are but slightly acted upon by pepsin. If further observation bears out these flattering accounts, we should possess in alginate of iron a compound of first-rate value in therapeutics.

Most of us at one time or another have been at our wit's end for some new suggestion in treatment to employ in cases of Graves' disease after the orthodox list of remedies has been tested and has failed. Semple speaks favorably in the *British Medico-Chirurgical Journal* of a combination of the Schott treatment with Weir Mitchell treatment, aided and abetted by drugs and careful regimen. It is hard to see how we can look for curative effects from such a combination, seeing that the circulatory disorders are only a small part of the disease. We have recently employed suprarenal extract in several cases of Graves' disease with marked benefit to all the symptoms, even the thyroidal tumor. We have no doubt that great benefit to the condition of heart-hurry and heart weakness may be thus obtained in a

very large number of cases, and if as is possible the exophthalmus and thyroidal tumor be due respectively to dilatation of the retrobulbar and thyroidal arteries, the use of so powerful a vasoconstrictor is not without support in rational therapeutics. Now that pathologists are convinced that Graves' disease is to a very large degree a psychosis, one can hardly look for cure from remedies that at best tickle the periphery, while leaving untouched the *primum mobile*—the psychical disorder—that underlies the disease. Rest of mind, freedom from worry, and allaying of the ever-present apprehension are the first essentials in treatment; rest of body, careful regimen and drugs are only useful in so far as they minister to tranquillity of mind by improving the general well-being. The very common association of rheumatism with Graves' disease is of much interest viewed along with its very common association with chorea. In the latter disease we almost certainly have to deal with disordered equilibrium of the cortical motor cells, so that they discharge in an ill-restrained manner. May it not be that rheumatism also predisposes to the psychical disorder, which consummates in Graves' disease, by this selfsame effect on the cortical cells? Of late years influenza has appeared in not a few cases as the immediate precursor of Graves' disease; may we not look to the same locality for an explanation of this conjunction? For such reasons as these we can only regard as a palliative any remedy that is not primarily directed to the relief of the central nervous disturbance.

Among books of note that have been published recently in this country we would specially call attention to a Manual of Surgery by Rose and Carters. A happier combination could not have been found than these disciples respectively of Sir William Ferguson and Lord Lister. The volume provides a very large amount of knowledge in a very succinct form and free from the faults that usually result from compression. We can heartily recommend the volume to students of all classes, and also to the general practitioner whose interest in his profession has not died with the attainment of a diploma.

Sir William Stokes, Bart., surgeon-in-ordinary to Her Majesty the Queen in Ireland, reported upon thyroidectomy in exophthalmic goitre to the recent meeting of the British Medical Association. He thought the following case worthy of record, inasmuch as it lends color to one of the many theories of

the causation of this disease that have been propounded from time to time: G. D., aged thirty-two, was admitted to the Meath Hospital under the care of Dr. Craig in October, 1894. The clinical condition presented the familiar features and was definitely attributed to a fright from seeing a friend of his killed by a threshing machine. He was treated with ergotin and belladonna, and subsequently with thyroid extract. His general health became much improved, the tumor in the neck decreased in size, the eyes became less prominent, and the tremor subsided. The improvement, however, was only temporary, and he was readmitted to the hospital in May, 1896, with an aggravation of all the existing symptoms. The patient was then anemic. The thyroid was enlarged, particularly the central lobe, which was about the size of a large Tangerine orange; the lateral lobes were also somewhat enlarged. The circumference of the neck at the most prominent part of the enlargement was eighteen inches. There was a systolic murmur heard over the gland and a bruit in the vessels of the neck. The heart's action was very irregular, but not very fast, and there was a slight trace of a systolic murmur in the mitral area. This was probably hemic in character, as it was not constant and disappeared on excitement. The eyes were prominent, the palpebral orifice enlarged, and there was well marked nystagmus; neither von Graefe's nor Stelwag's signs were well marked. There was tremor, but no skin pigmentation; no local nor general edema; the urine was normal. Sir William Stokes at this stage removed the large central tumor. A smaller growth about the size of a pigeon's egg was found lying to the right, but on a posterior plane; this was also removed, and with it a portion of the right lobe of the thyroid. The only feature of special interest in the course of the operation was paroxysms of alarming dyspnea; while after the operation severe syncopal attacks accompanied by profuse sweating necessitated the constant use of diffusible stimulants. In three weeks the patient was able to leave the hospital with marked amelioration of all his symptoms. In many respects the case runs parallel to that published by Lord Lister in 1877, although there was none of that mechanical compression by the tumor which in his case threatened life by suffocation.

In reference to the therapeutics of this malady we find as great diversity of opinion

as in regard to its etiology and pathology. Professor Bruns (*Berl. Klin. Wochens.*, 1896, p. 406) holds that it is quite exceptional for the goitre to diminish under the administration of thyroid preparations, and that under their influence the cardiac and nervous symptoms as a rule get worse. The simple hyperplastic form of goitre appears to be the one that is specially amenable to thyroid medication. Among physicians there is pretty general agreement that treatment by thymus gland is entirely useless. Dr. Hector Mackenzie finds "that the thymus gland possesses no specific action in Graves' disease. I have found it in most cases to have no effect either on the heart, on the goitre, or on the exophthalmus." The results obtained by operative treatment point distinctly, in Sir William Stokes' opinion, to the thyroid being the seat of the primary lesion. For example, Lemke, of Hamburg, who is a strong opponent of the neuropathic nature of Graves' disease, believing that the symptoms are due to toxic agencies originating in the thyroid gland, strongly advocates surgical treatment. M. Allen Starr (*Medical News*, April 18, 1896) has published a statistical record of 190 cases, a large proportion of which were permanently benefited by operation: seventy-four are reported as cured, forty-five improved, and three not benefited. He states that twenty-three of the cases died immediately after the operation, which could not be attributed either to hemorrhage or sepsis. He attributes the calamity to a poisoning of the entire system by absorption of thyroid juice during the operation. This he thinks may result from an excessive handling of the tumor during operation, from "absorption of torn vessels, or hypersecretion due to the employment of ether as an anesthetic." He suggests, therefore, that some other anesthetic should preferably be employed, and mentions cocaine as recommended by Kocher. The symptoms preceding death were those of collapse and cardiac failure.

Among other methods of operative treatment adopted in these cases mention should be made of Trousseau's suggestion of local depletion, also Jaboulay's exothyropexy, which consists in stripping the capsule from the gland and fixing the latter in the superficial wound so as to produce shrinking from exposure to air and from thrombosis of the venous sinuses. Also division of the cervical sympathetic has been suggested, and ligature of the thyroid arteries. Of drugs we may take Osler's estimate that all are "notori-

ously uncertain." Sir William Stokes claims in regard to the case he communicates that as two years have elapsed since the operation without any recurrence of the symptoms, the treatment adopted may be considered as successful.

Professor Mayo Robson (Leeds) read a paper on a series of cases of choledochotomy; including three of duodenocholedochotomy. He remarked that at the present time it may be confidently asserted that there is no portion of the gall-bladder, cystic, common or primary divisions of the hepatic ducts, which cannot under ordinary circumstances be reached for the removal of gall-stones, and that in operating on the gall-bladder and bile-ducts it is better to begin with an open mind, prepared for any of the various operations on the biliary passages, as it is usually impossible to say what may be required until the ducts have been explored by the fingers and the condition of the parts ascertained. After describing the various operations which may be employed for the removal of gall-stones from the common duct, he proceeded to consider some of the details of the operation—some of the said points being the placing of a sand-bag under the back before operating, which brings the common duct nearer to the surface; exploring the common duct when possible by the finger introduced through the incision in the duct so as to avoid leaving concretions; and the administration of chloride of calcium before and after operation in order to avoid the bleeding which is so apt to occur in deeply jaundiced patients.

In remarking on the prognosis, Robson said that he had operated directly for gall-stones in the common duct in forty-nine cases, with three deaths, giving a mortality of 6.1 per cent. These deaths occurred, one after cholecystenterostomy and two after choledochotomy, and in all three the jaundice had been long-continued and deep and associated with infective or suppurative cholangioitis. After choledochotomy he had not had a death.

The author gave a table with a brief history of seventeen choledochotomies which he had performed, and concluded his remarks by saying that as experience increased he hoped and believed that the mortality in choledochotomy would be reduced to five per cent., though even if it should remain higher, it must be borne in mind that nearly every recovery is a life saved, for in the greater number of these cases of gall-stones in the

common duct death after prolonged suffering is the usual termination.

Robson also read a paper on three cases of partial hepatectomy for cancer. He remarked that out of nearly 300 operations on the liver and bile-ducts, he had operated in one way or another on thirty-five cases of malignant disease, but out of this number he had only met with three cases in which it seemed feasible to attempt complete removal of the disease by taking away the gall-bladder and the adjoining part of the liver. Of these three, one died shortly after operation from shock. The other two completely recovered from the operation, but only survived a few months before there was a recurrence of the disease. The method he had adopted in all the cases was to apply an elastic ligature below pins which transfixed the cystic duct and the liver tissue.

The author remarked that it was a curious fact that in two cases where he had closed the abdomen, thinking the disease to be malignant, and where in one case cholecystotomy had been done and in another a simple exploratory incision, complete and permanent recovery had followed. It was of course possible that these cases had not been malignant. On the other hand, the question was raised as to whether they should not come under the class of cases of cure by operation *per se*. He advised exploration in all doubtful cases, if in a condition to bear it, since in several he had found the disease, previously thought to be cancer, to be inflammatory, and the patients had been completely cured by operation.

In conclusion the author expressed the following opinions:

1. Seeing that statistics from various countries and by many observers agree in showing the frequent association of gall-stones and primary cancer of the gall-bladder and liver, it is desirable that cases of cholelithiasis should be submitted to surgical treatment at an earlier stage than has hitherto been the custom.

2. In all cases of tumor of the gall-bladder, even if unaccompanied by symptoms, an operation should be advised and the obstruction, usually a calculus, should be removed.

3. If these rules were followed, primary cancer of the gall-bladder and liver would probably be less frequent.

4. If early operation in cases of tumor of the gall-bladder were followed out, even if primary cancer had commenced, it could be caught in an incipient stage, when a com-

plete cure by partial hepatectomy might be reasonably hoped for.

5. An exploratory operation, even in a patient seriously ill with a localized tumor in the gall-bladder region, is worth advocating though malignant disease be feared, in the hope that the disease may be inflammatory and so capable of relief.

6. If there are any secondary nodules in the liver, or if adjoining viscera are invaded, the operation had better be terminated as a simple exploratory one.

#### PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

Ever since the discovery by Eberth and Gaffky of the microbe of enteric fever pathologists have endeavored to bring about cases of infection in animals by the administration of the germ by the mouth. Not long ago Sanarelli, after having treated various animals with the toxin of enteric fever, had come to the following conclusions, namely, that the pathological alterations to be found on the surface of the intestine in this affection are not directly caused by the microbe, but are the result of its toxins—*i.e.*, the bacillus taken into the system causes necrosis of Peyer's patches by means of its toxin.

Professor Chantemesse, of Paris, who has devoted much time to the consideration of the question of enteric fever, and Dr. Ramond, former house physician of the Paris hospitals, seem to have succeeded in infecting animals with enteric fever. In a first series of animals they sprinkled the food with a virulent culture of the bacilli. Twelve rabbits treated in this way showed mild symptoms of infection. They all recovered in from fifteen to eighteen days. It is necessary, however, to lower the resistance of the animals, which may be done by injecting daily three or four cubic centimeters of blood serum taken from men who have never suffered from enteric fever. Another method consisted in the injection of fifty drops of laudanum into the peritoneal cavity a few minutes before the ingestion of the bacilli. Cultures of the bacilli may not only be mixed with the food, but may be passed directly into the stomach by means of a rubber tube.

Shortly after the administration of a recent culture the animal's temperature would rise to 40° or 41° C., and it would lose its appetite. Its weight would soon fall about 150 to 200 grammes. The temperature, after the

first rise, would remain but a few tenths of a degree above the normal, but on the twelfth day would again suddenly rise to 40° C. and remain high for about fifteen days. During this period not only would the appetite be diminished, but some irregular diarrhea would be present, while the respiration would be slower. No albumen was to be found in the urine.

The animal would lie more or less huddled up, with its eyes half closed and its ears hanging down. In some cases a rapid recovery took place, but in a few others the animal died from peritonitis or typhoid septicemia. In other cases the symptoms were slight, consisting only in some fever, diarrhea, and loss of flesh. At the beginning of the second week a distinct sero-reaction was to be noted, lasting two months after recovery.

Autopsies of the animals deceased revealed pathological alterations similar to those found in enteric fever, namely, congestion and infiltration of Peyer's patches, with slight traces of hemorrhage. Some well defined ulcerations were present; the mesenteric lymphatic glands were found swollen; the spleen was enlarged and dark, and the liver was congested. Broncho-pulmonary and pleural lesions were of frequent occurrence.

Microscopic examination revealed the presence of bacilli in the follicles of the intestine, where they were extremely abundant; more deeply they seemed to tend to break up into granules. Some succeeded in reaching the mesenteric glands, where the sinuses were filled with them, grouped infrequently into masses of twelve to fifteen bacilli, surrounded by amorphous substance.

Drs. Chantemesse and Ramond were led to conclude from these experiments that in enteric fever in animals there occurred first of all a lymphatic stage, corresponding perhaps to the incubatory period. In this stage the bacillus invades the follicles and gets as far as the mesenteric glands. In a second stage, of short duration, general circulatory infection occurs, followed by localization in the spleen and liver—the visceral stage.

It was noted that the infection did not act to any great extent upon the kidneys, a fact due to the disease being less virulent in animals, and to the uncommonness of secondary infections which affect the renal functions much more than does the toxin of enteric fever. Such a condition is seen to a certain extent in children suffering from enteric fever, as they are less exposed than adults to secondary infections.

The Fourth Congress on Tuberculosis was held in Paris from July 27 to August 3. The members of the Congress were taken over the Boucicaut Hospital, the recently opened establishment built thanks to the endowment furnished by Madame Boucicaut, the late proprietress of the Bon Marché. They inspected the wards for tuberculous patients, and Dr. Ribard, one of the physicians of the hospital, explained his treatment for anorexia in tuberculous patients. It consists in applying two kilogrammes of carbonic acid snow to the pit of the stomach or over the liver just before meals. The snow is enclosed in a bag and surrounded by a thick layer of wadding.

The first meeting was held in the great amphitheater of the Faculty of Medicine, at three o'clock in the afternoon of July 27. Dr. Nocard, a veterinary surgeon, who was president of the Congress, spoke at length on the necessity of stringent regulations against bovine tuberculosis, and called attention to the results obtained in Denmark, where tuberculosis had been so prevalent among cattle.

Dr. Petit, secretary to the Congress, spoke of the results achieved since the previous congress. In the public schools some efforts had been made to place spittoons in the halls and stairways, and to prevent pupils from expectorating on the floor. So far declaration of cases of tuberculosis by the physician has not been made obligatory, and it is not likely to be made so, from the fact that such a measure was not advocated in the recent report published by the Academy of Medicine. In some of the hospitals wards specially reserved for tuberculous patients have been opened. The speaker called attention to the societies founded in other countries, the Red Cross in Berlin, and to the aid given them by the Empress Mary of Russia, the Czar Nicholas II, the Kings of Denmark and Sweden. Dr. Petit ended his speech by thanking the members of the Congress for their presence.

Two of the most important communications made to the Congress were a report by Dr. Landouzy, Professor of Therapeutics at the Faculty of Paris, on the treatment of tuberculosis by serums and toxins, and a report on the "Hospitalization of Indigent Tuberculous Patients in Paris," by Dr. Letulle, one of the physicians of the Boucicaut Hospital.

Dr. Letulle began by declaring that it was a fact that tuberculous patients without means were treated in Paris with a well-

nigh complete lack of the hygienic precautions necessary in such cases. He called attention to the fact that the means used to prevent the spread of tuberculosis, namely, isolation and disinfection, were not only capable of resisting its extension, but contributed likewise to arrest its progress in patients already suffering from it. By the installation of special wards for tuberculous patients the treatment could be modified; the quantity of air for each patient was increased; no supplementary beds were allowed, nor the use of brooms or dusters; in brief, the causes of secondary infection were put aside.

In November, 1897, Dr. Letulle reserved two wards, containing in all thirty-five beds, for tuberculous patients. During a period of eight months 125 patients were treated. Thirty-eight deaths occurred, sixty cases grew worse, and twenty-seven cases increased in weight and showed improvement. The patients were weighed every week at a certain hour, and in some cases an increase of from four to ten kilogrammes was noted. Dr. Letulle thought that these encouraging results were due to a treatment based on two principles. The first consisted in rigorous asepsis of the service. This should be more stringent than in surgical wards even, as the patients are more liable to infection. Spittoons were placed everywhere. No ordinary handkerchiefs were allowed; they were replaced by sterilized compresses. The patients were bathed and cleaned before entering the wards. In brief, the only danger left was due to visits from friends and relatives. The second principle of the treatment consisted in good air, rest, and good food.

The windows of the wards were open night and day. These windows are divided into three parts, and the upper part only was left open at night. The patients were kept out-of-doors as much as possible. Two tents have been placed in the garden, containing inclined chairs, and the patients are sent out from half-past five to nine o'clock in the morning, and from half-past five to nine in the evening. When the sun is not too hot, the patients were sent out from 12 M. to 5 in the afternoon.

So far the cure by suralimentation has been rather elementary in the Paris hospitals. The patients were given the first, second or fourth degrees of diet according to their condition, and in certain cases milk, fresh eggs, raw or powdered meat were added. A change

has been brought about at the Boucicaut Hospital, and the patients now have five meals a day. The relatives and friends of the patients are requested to leave off bringing sweets, and a list is furnished them showing what articles of food they may bring.

Dr. Vitaliani recommends a simple and efficacious means of treating blisters caused by badly fitting shoes. The blister should be incised from end to end, and when the serosity has disappeared, a little iodoform should be dusted in by lifting up each flap of the blister. A small quantity of absorbent cotton should be applied and kept in place with some adhesive plaster. The patient can then put on his shoe and continue walking. In less than a day the wound has dried and there is a new layer of epidermis.

#### BERLIN LETTER.

By JAMES J. WALSH, M.D., PH.D.

Two things were of interest from a therapeutic standpoint in Professor Koch's talk on the spread of the bubonic plague. His thorough confidence in the preventive therapeutics of modern quarantine, now that we know exactly whence to look for the danger, and his description of the portion of the Uganda country in which the plague has been endemic for so long as tradition runs, is worthy of note.

Koch does not think that there is any serious danger now of the plague ever again overrunning civilized countries. The conditions of its contagion are such that with reasonably sanitary surroundings, ordinary quarantine regulations will always be sufficient to protect civilization from invasion. Mesopotamia, Thibet and the Arabian coast just below Mecca were the real plague spots where the disease was known to be endemic; to these are now added the Uganda country on the northern shores of Lake Victoria Nyanza, hitherto unsuspected in this regard, but from which undoubtedly epidemics have come down the Nile to invade Europe. From here doubtless Tripoli received the germs of the fatal epidemic of the early seventies, the origin of which has been hitherto a mystery. If a jealous eye is kept on these regions Koch thinks there need never be fear of another great epidemic.

The part of Central Africa in which the plague is endemic is in the midst of the banana groves of the Uganda country, not far from the shores of Lake Victoria Nyanza.

The people live practically exclusively on bananas. Their huts are in banana groves so thickly overgrown that scarcely a ray of light penetrates and the ground is always damp. The air is overloaded with moisture. The groves are infested with innumerable rats. Here are all the conditions favorable for the development of lower plant life in a luxuriance that may easily change the character of it from harmless to harmful. The presence of the rats gives a preliminary host to still further increase the virulence of the micro-organism. For the plague is a rat disease, not a human disease. These usually intensely resistant animals succumb to it at once. Mere contact communicates it to them, while other animals must be inoculated with it. Men are only secondarily the victims, after the passage of the virus through animals has increased its virulence.

I have heard two authoritative statements recently that seem to show that after the recent period of pathological interest in the gonococcus, that finally placed that eminently disagreeable being on a pinnacle of etiological activity beyond that of most other microbes in the extent and severity of the pathological changes it could induce, the inevitable reaction is setting in. These two statements set it in a much lower plane of virulence than even ordinary pus micro-organisms. Professor Lassar stated that he had never seen an epididymitis occur in a case of gonorrhea that had not been treated. To his mind the complications of gonorrhea that occurred three to five weeks after infection, but especially the epididymitis, were the result of secondary infection. How that secondary infection was acquired was easy to explain. Patients absolutely without an idea of asepsis were furnished with a syringe, for using which they were given no directions as to cleanliness, often not even warned of the danger of uncleanness. Injections were given by patients in all sorts of out-of-the-way places, usually the very opposite of aseptic in character. The syringe and solution for injection were carried around in the pocket, and usually there was no chance to even wash the hands before administering the injection. It is foolish to think that under such circumstances, because the solution is an antiseptic, the patient is free from the danger of secondary infection. Antiseptics as injected into the urethra were always so weak as to scarcely affect micro-organisms, unless allowed to act during long periods, and were usually such as were sup-

posed to have a value because especially inhibitory to the gonococcus.

The other statement was from Professor Gusserow's assistant at the Charité, Dr. Volkmann. In discussing the causes of uterine bleeding, during a discussion at a meeting of the Charité Aerzte, he called attention to the fact, insisted on by Säger, that a gonorrheal oophoritis is often accompanied by menstrual disturbances, the periods becoming more frequent and more blood being lost. Gynecologically he considers this to be of the greatest importance, for infection with the gonococcus practically never leads to peritonitis, and the lesions gradually undergo a process of involution that makes them harmless. If, then, a patient comes with a history of bleedings after the recurrence of symptoms of a gonorrhea and her ovaries be found affected, there will scarcely be question of surgical interference in the case, for as a rule Nature is well able to take care of the patient in the matter.

The Pasteur treatment for rabies was begun in the Institute for Infectious Diseases, Professor Koch's department at the Charité, in the beginning of July. Eight cases were under treatment during the first month. As Professor Brieger (Professor Koch's assistant) says, there was evidently need for the new establishment. He says that the statistics from Russia and from Austria, where national feeling has no weight in the matter, amply justify the claim that the Pasteur treatment is an effective therapeutic method. One thing is now certain, viz., that the treatment is absolutely harmless. As Berlin has been the great stronghold of opposition to the Pasteur treatment, and especially emphatic as to the danger of communicating the disease it was supposed to cure, it would seem that the last word in the chapter of opposition to Pasteur's great discovery has been written. The introduction of the treatment at Berlin will be the signal for each of the German universities to establish a Pasteur institute, and the new century will find the treatment in universal use.

One of the abominations that one does not have persistently forced on his attention over here is the chewing of gum. Professor Ewald, however, recommends it as a therapeutic measure in certain stomach diseases, not because of any supposed minimal pepsin addition, but for its mechanical action in causing a superabundant flow of saliva. In certain nervous states accompanied by an excessive secretion of hydrochloric acid, the

flow of alkaline saliva tends to neutralize the acidity and so do away with a number of symptoms, like continuous urgent hunger, relieved only for a short time by taking food, that occur in gastric hyperchlorhydria.

#### LETTER FROM THE FRONT.

BY EDWARD MARTIN, M.D.

To the Editor of the THERAPEUTIC GAZETTE.

SIR: When, at the beginning of the present war in the latter part of April, the State troops were ordered out, those from Pennsylvania, about eight thousand strong, were sent to Mt. Gretna, a high, well watered region near Harrisburg. The Philadelphia regiments, presumably the least accustomed to stress of weather, moved out on the morning of a cold wet day, the snow which fell early changing to a heavy rain later. Some of them, after an all-day railway journey, were compelled to bivouac for the night, neither ground nor tents being assigned to them sufficiently early to allow of shelter being provided. These troops were improperly shod, inadequately clothed, and somewhat irregularly fed; they were taken in part from workshops and from sedentary occupations; they were exposed to many days of cold, almost ceaseless, rain, transforming the camp into a sea of mud; the nights were always cold, frost falling at times. With these conditions obtaining, many not too robust, house-softened men, always with wet feet, generally with wet clothing, always cold at night, given food to which they were not accustomed, the regimental surgeons naturally looked to having their hospitals full of men seriously ill with rheumatic affections, particularly acute articular and muscular rheumatism, and acute congestions from surface chilling, particularly bronchitis, pneumonia, and diarrhea.

To the surprise of every one there was almost no sickness of any kind, far less than I have ever known in any summer encampment. I believe the reasons for this were: (1) The stimulating effect of the excitement incident to the beginning of actual war, and the daily expectation of orders to move; (2) the bracing effect of the fresh mountain air; (3) the coolness of the weather—northern men always stand cold better than heat; (4) the simple diet—there were almost no booths selling ice cream, milk shake, soda water, and fruit, always prolific sources of camp diarrhea. After about two weeks of cold, wet, and discomfort, but generally of excellent

health, a portion of the troops were ordered to Chickamauga, Ga. This also is in a mountainous region, but is hot in the day and dry, absolutely no mountain springs running through it, dusty beyond all experience elsewhere, cools rapidly at night but does not become actually cold, with the deposition of a dew so heavy that as it dropped from the trees upon our tent roofs it sounded as would a beginning rain-storm. The water-supply here was surface water—*i.e.*, was pumped from wells twenty or thirty feet deep. Some ran deeper, but were not true Artesian wells. The food issued was more irregular than ever before, and the water was so inadequate in quantity that there were constant quarrels about the wells. The heat during the day was so intense that one of our men was sun-struck, and nearly every morning and evening drill saw many instances of heat prostration. Moreover, the mixed soft drink and fruit wagon and stand abounded.

Medically our troubles began at Chickamauga. On the night of our arrival the men were compelled to bivouac, the train getting in too late to allow of reaching the camping ground and putting up canvas. Everything exposed to the dew was nearly as wet as it would have been had there been rain. The next morning was close and very hot, and after a light breakfast, mainly of coffee, the regiment was taken in heavy marching order (this means each man carrying about sixty pounds) to the camping ground about two and a half miles away. The route was over a road several inches thick with dust. It was at the end of this march that the case of sunstroke occurred, also a number of cases of heat exhaustion. On the following morning, at sick call, in place of the four or five men who had been coming, with slight injuries or ailments, I found some forty or fifty men. Nearly all of them were suffering from a harassing cough. The physical signs, those of a slight bronchitis, were by no means commensurate with the severity and persistence of the cough; there was little or no fever, no diminution of the appetite, a distressing sore throat, tenderness on swallowing, inconspicuous faucial lesions, soreness and rawness along the line of the trachea, much abdominal soreness (from the incessant cough, which greatly interrupted sleep), and no pulse hurry. This was the type of an epidemic which made no great headway but which yielded not in the slightest to the ordinary sedative treatment. They were given "Brown mixture" alone, or ammonium muriate, pare-

goric, opium, laudanum, codeine sulphate, morphine sulphate, sodium and potassium bromide, Dover's powder, gargles (astringent, antiseptic, and sedative), sprays and inhalations, without the slightest effect. Copaiba and sandalwood were equally inefficacious. The first obvious improvement followed the free use of counter-irritation to the chest, along the line of the trachea, and to the neck. This was accomplished by mustard plaster and tincture of iodine. Finally we struck upon the following formula:

R Terebene,  
Oil of eucalyptus, aa ʒ j;  
Syrup of yerba santa, ʒ j.

M. S.: One teaspoonful every two or three hours.

The effect was prompt and thoroughly satisfactory; in three days the camp became fairly quiet at night, and by the end of the week there lingered only a very few cases, all rapidly growing better.

Toward the end of our stay in Chickamauga the men began to suffer from diarrhea, usually, but not always, traceable to fruit-eating or taking of large quantities of iced drinks immediately after drill. At Chickamauga the most troublesome illness was undoubtedly a harassing inflammation of the mucous membrane of the throat, larynx, and larger bronchial tubes. This was due to: (1) The dust made by the heavy hauling over the fine park roads; the air was constantly full of it, and it formed an impalpable powder rendering everything filthy. (2) The sudden contrast between the hot days and the cool, wet evenings. Fewer colds were contracted after we insisted on the men putting on their blouses at sunset.

The surface water supply should have given trouble particularly after the ground had been camped on for some weeks, but up to the time of our leaving (the end of May) it had not done so, for but one case of typhoid fever developed. In the beginning of June we were ordered to Tampa, famed even in song as a breeding-place for fever.

The camps were pitched in a sandy soil, were partly shaded by a thin growth of pine, and were in the main near enough to the water to enable the soldiers to bathe regularly. The usual disposition of all waste about a camp, including in this term the feces, of which there will be daily about a half ton to a regiment, is to bury it. Even before the tents are put up and as soon as the location of the camp is definitely determined and the company streets are marked out, there is dug at least twenty yards behind

the line of kitchens a series of trenches ten feet wide and three to four feet deep and twenty feet long, for each company, to receive the feces. These trenches are usually provided with a log or scantling seat and are often partially screened by pine branches or bushes. Similar provision is made for the officers at their end of the camp. Near each cook-shed, one to a company, a hole is dug about four feet square and the same depth; this is to receive the kitchen refuse, at least all that is not burned—no rubbish of any kind is allowed about the camp or its environs. The pits for refuse of all kinds are covered at least twice a day. In my own camp there was provided a shovel at each pit, and the moment anything was dropped in it was covered with a shovelful of sand; this entirely did away with the disagreeable odor which usually characterizes garbage holes, and materially lessened their danger as breeders of flies. When the pits are covered to within two feet of the surface they are piled up level and new ones are dug. It is evident that when the surface water from or near the camp is not used for drinking purposes this provides an easy, excellent and safe means for getting rid of the feces and garbage. In low-lying regions the water is often found within two feet of the surface; the pit system then becomes troublesome and dangerous, since new trenches must be dug daily and the layer of earth overlying the excrementitious materials is not sufficiently thick to prevent the escape of offensive gases.

In large camps the water is commonly supplied by pipes bringing it from a distance and running somewhere near the line of company kitchens. This was the case at Tampa. The Plant system hauled part of their water, the larger part; the rest was piped to the soldiers from a spring. It contained much iron, turning a tumbler yellow on standing, but after boiling and filtration it was good. The evil taste and appearance of the water, however, induced many of the soldiers to seek what they deemed a better and safer supply from some of the many surface wells. This they did at first in spite of orders, and to their ultimate disadvantage.

The conditions confronting us at Tampa were: (1) A tropical climate, but with the water so near that the nights were nearly always breezy and cool. The dewfall was slight. (2) A sandy soil with the water so near the surface that in some locations the trenches could not be dug more than two feet deep. (3) The proximity of large fresh-

water ponds. (4) An adequate and healthful water-supply, but so unpleasing to the eye and taste that there was a tendency on the part of the privates to prefer the better looking water from shallow wells. (5) A city in which there is always some typhoid and malarial fever. (6) Drinks of all kinds fairly accessible, fruit abundant, cheap, and bad.

The causes of disability we could fairly expect to be most prominent were heat exhaustion and sunstroke during the acclimating drills, malarial fever, diarrhea and dysentery, later typhoid fever.

With the exception of heat exhaustion, of which we had but few cases, and sunstroke, of which we had none, our expectations were fairly fulfilled. After the first week, when every one was buoyed up by the hope of going immediately aboard transports, there was a rapid increase in the number of men reporting for relief from duty. In over ninety per cent. the affection was diarrhea, sometimes painless, often attended by severe, occasionally by agonizing, cramps, usually afebrile, accompanied only exceptionally by nausea and vomiting, attended by great weakness, especially when there was accompanying fever, yielding rather slowly to treatment unless this was accompanied by rest in bed. In a command of six hundred men there would be sixty of a morning presenting these symptoms. A smaller number would give a history of violent straining and the passage of blood-stained mucus.

The treatment which gave the best results in these cases was: (1) Entire abstinence from everything but water or tea for one, two or three days; (2) rest in quarters or in hospital, the latter always when the affection persisted more than two days; (3) the wearing of a belly-band, preceded by a large mustard plaster; (4) the immediate administration in cases of moderate pain of tincture of ginger half a drachm, subnitrate of bismuth half a drachm; when the pain was severe chlor-anodyne or chlorodyne fifteen minims, when it was agonizing a hypodermic injection of a quarter of a grain of morphine. In all cases salol was given commonly associated with oil of peppermint and bismuth, small doses being repeated hourly; commonly we gave four grains of salol and thirty grains of bismuth subnitrate every two or three hours, often combining the bismuth with ginger. When there was much nausea and vomiting we gave calomel and soda, a sixth of a grain of the former and two grains of the latter,

hourly, for six doses. In the very beginning of a severe attack we had excellent results from chlor-anodyne or chlorodyne fifteen minims and castor oil one ounce. The regular army prescription, camphor and opium pills, we used but little and always in conjunction with intestinal antiseptics, holding that the diarrhea was usually eliminative and that the first effect to be produced was to disinfect the fermenting gastric and intestinal contents. We also counseled the men to vomit the moment they felt the beginning of an acute indigestion.

A part of the diarrhea we could directly trace to an inordinate consumption of green coffee, a part to a not sufficiently varied diet, but most of it to the fruit and iced drink stands which sprang up like mushrooms about the camp. The errors in diet were in the main corrected, the fruit stands included, when there resulted a marked and immediate diminution in the number of cases of acute diarrhea and gastro-enteritis. Later in the summer, after the troops had been in Tampa for upwards of a month and the rainy season had fairly started, the malarial and typhoid fevers became unpleasantly prominent. There was comparatively little of the typical malarial attacks characterized by periodically recurring chill, fever, and sweat, with an intervening afebrile period. The fever was remittent in type, was accompanied by marked gastro-enteric disturbances, often by an obstinate diarrhea, was at times intractable to quinine, and in a few instances resulted fatally. The usual treatment was pursued — *i.e.*, the use of calomel to disinfect and clean the gastro-intestinal tract, followed by quinine. The fever yielded, but on returning the soldiers to duty would recur. The typhoid fever was severe in type. It was certainly contracted from well-water, either obtained in camp because of its supposed purity, or given to the men by some of the many vendors of soft drinks. It could perhaps have been prevented. The means naturally suggested in the light of this experience are:

1. The further education of the troops through their company officers as to the importance of drinking only boiled water.

2. Careful attention on the part of the company officer to the securing of means by which the water for drinking may be regularly boiled and stored, and daily inspection of the reservoirs by the medical officer made.

3. Either the abolition of all soft drink stands or a daily medical inspection of them

so that only boiled water and artificial ice may be used.

4. The constant guarding of all wells, springs or other sources of water-supply than those provided for the camp and known to be pure, as a further means of preventing typhoid fever or at least of preventing the gastro-enteric congestion which seems to favor its development; the unguarded use of ice water or of iced drinks of any kind should be forbidden, except for storing purposes and in cases of sickness. The troops would be better without ice. The large quantities of very cold water taken when the men come in hot from drill were responsible for many cases of acute diarrhea.

It is probable that could the troops be trained to drink only boiled water, not only would typhoid fever disappear from among them, but malarial fever would become much less frequent. With the advent of Artesian drinking-water through the South the severe forms of malaria previously prevalent are disappearing, thus showing that the malarial poison is often taken into the system with the drinking-water.

One of the stirring scenes of the camp was the coming in of the *Cherokee* with between three and four hundred of the soldiers who had been wounded in the fighting about Santiago. None died on the voyage over and very few afterward. The great majority recovered promptly and without suppuration. The Mauser bullet, about thirty caliber, is an exceedingly merciful one. The wounds made by it I saw when about nine days old; they were small, mostly healed and slightly scabbed punctures looking much like a scratched and scabbed mosquito bite. The wound of exit was not in the least different from the wound of entrance; there were no evidences of that explosive force which the modern projectile is supposed to exhibit at short and long range, and which our own Kräg-Jorgensen rifle bullet certainly does exhibit in experiments on the cadaver. Some men were shot at forty yards, some at twelve hundred; the wounds looked the same. In a number of instances the balls had remained in the tissues and had been extracted. Two patients whom I saw were shot directly through the lung. One spat blood for a day, but he was also shot at the same time through the neck and the floor of the mouth by the same ball, he says; the other had no bloody expectoration. These men were walking about with healed wounds. All the wounded seemed strong and cheerful. There was a striking absence of the hospital

facies and the feeble bearing to which we are accustomed in patients who are hurt and who are taken to our city hospitals. From surgeons on the field who had dressed hundreds of the wounded I learned: (1) There was almost no evidence of an explosive action of the Mauser bullet; it generally made a clean-drilled hole, going through all tissues, even bone, without shattering it. (2) When it hit a man it usually stopped him; this was not always the case. (3) There were some cases shot through the head and some shot through the belly which recovered. (4) The killed were hit in a vital part, the brain or head, or a great blood-vessel; many were torn by shrapnel or the missiles from rapid-fire guns. The proportion of wounded men to killed was very large. (5) There was very little hemorrhage either primary or secondary. (6) There was almost no operating other than that having for its object the cleansing and dressing of wounds. There were not more than a dozen amputations in all. (7) There was very little systemic shock from the Mauser bullet wounds. When a first-aid dressing was promptly applied the healing was usually without suppuration.

The value of this first-aid dressing of sterile gauze, one of which was carried by every soldier, was in part demonstrated by two suppurating cases, neither of which had had it applied. Though experimentally it cannot be shown that a bullet track is not sterile, practical experience proves that providing further infection can be kept out the track is likely to heal by first intention; the speedy way in which the wounds treated by the first-aid packets provided by the Army healed should do much to strengthen the confidence in them, which has been gradually weakened as a result of laboratory experiment and theoretical objections. A few of the wounds were inflicted by the Remington 45 brass-jacketed bullets used by the guerillas; these formed large suppurating tracks very different from that which marked the course of the Mauser bullets.

---

#### UNTOWARD EFFECTS OF CINCHONIDINE SALICYLATE.

To the Editor of the THERAPEUTIC GAZETTE.

SIR: Being unable in any of the books and journals at my disposal to find any mention of the untoward effects of cinchonidine salicylate, I think the following case that occurred in my practise recently is worth reporting:

Mrs. L. D. H., aged fifty, retired nurse, was suffering from an attack of neuritis which affected the median nerve of the right arm. Owing to the fact that her stomach had been most irritable for several years, and that the most simple article of food often upset it for days at a time, I tried to relieve the neuritis by external means rather than take the chances of upsetting the stomach, which under treatment was behaving fairly well.

No effect being had from the applications, I determined to use cinchonidine salicylate. Accordingly she was ordered ten grains of the drug three times a day. June 19, at 10.30 A.M., she took the first powder. An hour afterward she began to "feel queer," her head buzzed, and some nausea was present. As she felt much better after dinner she took another powder (at 2.30). About one hour later her head began to ache, vertigo became marked, the eyes watered profusely, a most severe pain affecting the face, jaw and limbs set in, and there was slight blurring of the vision. The patient felt very weak and relaxed. The bladder soon became a seat for the pains; urination became frequent, only a small amount of clear, almost colorless urine being voided each time; there was also a constant sense of fulness in the bladder.

At four o'clock the pains were so severe that she went to bed, and a short time afterward the face became so much swollen that she could not open her eyes. Nausea persisted until midnight, when she slept for nearly an hour. About noon the following day the pain in the head and face ceased, and the swelling had gone down somewhat. The bladder trouble continued, however, and on June 29 there was still some discomfort in that organ, but urination was less frequent.

One week from the time the powders were taken the swelling had disappeared, and the vision was as good as ever. As I did not see the patient during the acute attack I am unable to make any report as to the condition of the heart and pulse at that time.

Yours truly,

HENRY J. WALCOTT, JR., M.D.

BARRE, MASSACHUSETTS.

#### *APOCYNUM CANNABINUM.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: I wish to call your attention to a further point or two on *Apocynum Cannabinum*, concerning which you publish a letter from T. S. Dabney, M.D., in your June issue, re-

ferring to the same subject in the April issue. Dr. Dabney seems desirous to place the prior use of this remedy where it belongs, so I wish to give the wheel another turn backward.

Dr. John M. Scudder, of Cincinnati, Ohio, writing in March, 1865, of this plant, says: "In atonic or passive dropsy it is the best remedy I have ever employed—in fact, so great has been the success attending its use, that I have almost looked upon it as a specific. It makes but little difference where the effusion is, whether it is edema, anasarca, ascites, or hydrothorax, it seems to reach the lesion upon which the effusion depends, checking it, stimulating absorption, and removing the water by way of the kidneys. I have successfully treated all these forms of dropsy with it.

"In the treatment of hydrocephalus we have abundant evidence that it is about the only remedy upon which we can depend. A considerable number of cases are reported in which the disease was fully developed, and in which its use was followed by entire removal of the dropsical deposit and restoration to health. I have used it in acute hydrocephalus with marked advantage; it checks irritation of the brain, increases the secretion of the urine, and checks diarrhea.

"It is especially useful in disease of the spinal cord, in which there is irritation of the excito-motory system. In children we occasionally see a case in which there is marked spinal lesion, with a doughy, pallid skin, puffiness of the eyelids and other parts, and occasionally marked edema. In these cases the apocynum exerts a decided curative influence; the improvement being speedy, and continuing to complete restoration of health."

Dr. Scudder used from one drachm to one ounce of a good tincture to four ounces of water, and gave a teaspoonful of the mixture at a dose.

In a work on materia medica, written by the same author, and published in 1870, he says he has used *Apocynum Cannabinum* in the above named conditions during the past eighteen years, having learned its use from his teachers and predecessors, who ordinarily made a decoction of it.

My preceptor used it before and at the time I was studying in his office, and I myself have now used it nearly twenty-five years, and have found it an extremely valuable remedy when exhibited in proper cases.

Very truly yours,

C. L. GREGORY, M.D.

### THE RELIEF OF SYMPTOMS IN PULMONARY DISEASES BY DIRECT MEDICATION.

BY JOHN A. THOMPSON, M.D.,  
Cincinnati, Ohio.

General anesthesia hourly gives proof of the rapid and profound effect on the human body of drugs administered by inhalation. With this hourly demonstration of the effectiveness of the method, it is strange that physicians have used the pulmonary tract so little for the exhibition of remedies. The reason for this neglect of a valuable thera-

peutic measure is, probably, that the instruments employed have not been effective. Few drugs are volatile enough to be active when inhaled. The few that are sufficiently volatile are too transient in their effects to be of much value except in emergencies. The attempt to carry less volatile remedies directly into the lungs by means of inhalers, nebulizers, or sprays, has failed through the defects of the apparatus. By none of these methods can a sufficient quantity of the drug be carried into the lungs to produce any marked effect. It would seem, *a priori*, that success in this line of treatment was to be obtained by introducing into the bronchi drugs that do not irritate and that vaporize

slowly at the temperature of the body. Owing to the failure of nebulizers and inhalers, a number of laryngologists have been experimenting with the direct injection of remedies into the trachea.

There are few technical difficulties in this method. With the parts illuminated as in an ordinary application of medicines to the larynx, the curved tip of a laryngeal syringe is carried back over the glottis. While the patient takes a slow, deep inspiration, the remedy is injected between the vocal cords into the trachea. In the earlier treatments it is sometimes advisable to anesthetize the larynx with cocaine. Later, when the patient recovers from the nervous apprehension that is so often excited by manipulation about the throat, cocainization of the larynx is neither necessary nor advisable. Where the patient has sufficient self-control to breathe slowly, deeply and regularly with the laryngeal mirror in position, it is easy to inject solutions into the trachea without passing the tip of the syringe below the glottis. This latter method is not advisable in ordinary treatments. There is apt to be some injury to the parts in introducing the syringe between the cords, or in withdrawing it. Where cocaine is not employed, a reflex spasm is excited by the contact of the syringe that makes the treatment disagreeable and sometimes painful to the patient. This is not necessary if physician and patient cooperate, the latter breathing as directed and the former regulating his movements by those of the larynx.

The medicines to be used in tracheal injections are principally those which are slowly given off as vapor at the temperature of the body. Menthol and camphor take front rank on account of their action lessening congestion and producing a degree of local anesthesia. Thrown directly into the bronchi, they have a positive curative effect on inflammations either acute or chronic. By their anesthetic action they control cough longer and more efficiently than morphine will when given hypodermically. Chloral and guaiacol are especially efficient as antiseptics in suppurative cases. Weak solutions of chlorphenol have been exceedingly valuable in tubercular ulcerations. There are theoretical reasons for advising the use of oil of cloves, oil of cinnamon, and their congeners, but the author has had no experience with them. At the Cincinnati Branch Hospital for Consumptives, Dr. Lyle is using iodoform in oil. His idea is that the iodo-

form may be taken into the tissues as carbon is in anthracosis, and have an effect in preventing the extension of tubercular infiltration. It is too soon to say what the result will be. The vehicle employed for the solution or suspension of remedies must be some form of oil. The experiments of Downie have shown that aqueous or alcoholic solutions are too irritating to be used with safety. One of the light petroleum oils is generally used, but a pure olive oil can be substituted and theoretically is better than a mineral oil.

The greatest advantage to be gained by direct medication of the lungs is that we secure the local effect of the medicine without its acting on or through other organs. In bronchial inflammation we can lessen the congestion of the mucosa as certainly by this method as we can relieve congestion of the nasal membrane by sprays. The anesthetic action of the drugs employed, on the terminal filaments of the irritated nerves, controls cough more effectively than can be done in any other way. Where in chronic diseases there are septic or decomposing secretions in bronchi or cavities, the antiseptic action of medicines can be secured only by their direct application to the affected areas. If given by the stomach they are either decomposed or so diluted when they reach the parts involved that they are worthless. In bronchiectatic cavities, the effect of the direct injection of guaiacol is a revelation to those familiar only with older methods of treatment. The odor and the absorption of septic matter can be controlled in a few days in cases where internal medication has for years failed to accomplish this result. In tubercular cavities with secondary infection by germs of suppuration, local antiseptics lessens suppuration, fever, and night sweats.

Another advantage of the injection method in diseases of the lungs is that medicines are not altered in the digestive tract. We know little of the changes, even in familiar remedies, after their absorption from the stomach. We do not, in many instances, know their form when they reach the lungs. We know their effect only empirically. Our therapeutic knowledge becomes much more certain and we are better able to suit the remedy to the disease when we can apply it directly to the involved tissues.

One of the best reasons for using the direct injection method in pulmonary diseases is that medicines given in this way do not impair nutrition. Most of our expectorants have a deleterious action on the digestive

tract. In administering them we are choosing the lesser of two evils. In advanced cases of phthisis it is often a debatable question whether the strength of the patient will be most impaired by allowing the cough to continue or by administering narcotics to quiet the cough and allow the patient to sleep, but at the same time interfere with digestion and nutrition. With a proper choice of remedies by tracheal injection it is possible to relieve the cough more promptly than can be done by internal medication. The remedies administered by the lungs do not in any way interfere with the action of the digestive tract. On the contrary, the stimulant action of menthol and camphor seems to have a beneficial effect on the nutritive processes. The unpleasant and harmful secondary effects of narcotics can be entirely avoided by substituting tracheal injections for the classical cough mixtures.

In the Cincinnati Branch Hospital for Consumptives, cough mixtures containing opiates are not given to any patient strong enough to come to the treatment room for a tracheal injection. Cases of beginning tuberculosis where the cough is excessive, causing the patient to vomit foods and to lose sleep, are most favorable for this method. An injection of menthol and guaiacol in the evening will ordinarily allow the patient to eat a full dinner and get from six to eight hours' sleep before the paroxysms of cough again return. In long-standing cases of tuberculosis with secondary suppuration, the septic fever and the night sweats yield more readily to tracheal medication than to medicines administered by the stomach.

In the first stage of acute bronchitis where the membrane is intensely congested and dry, injections are not indicated. At this time they are painful and irritating. After the stage of secretion has been reached, the cough is relieved and convalescence very much hastened by the use of weak mixtures of menthol and camphor injected daily. In chronic bronchitis direct medication gives ideal results. In asthmatic attacks injections of large quantities of menthol solution will frequently relieve all symptoms for six or eight hours. The accompanying bronchitis is cured by the same treatment and the duration of the attack very much shortened. In pulmonary emphysema the chronic bronchitis which accompanies this condition can be cured and the paroxysms of cough and dyspnea very much lessened by properly selected remedies injected into the trachea.

In pulmonary syphilis with breaking down of gummatous deposits, the cavities can be cleansed and disinfected and healing promoted by tracheal injections in cases where constitutional medication has been thoroughly tried and has hopelessly failed.

The objections made to tracheal injections are that excessive cough is induced by the injection. This is a theoretical objection and is not borne out by the experience of those who have used this method for years. In a case not acutely inflamed at the time of injection, and if the solution is not too strong, there will be very little cough caused by the injection of from one to four drachms of the solution. It is only occasionally that any pain is caused by the injection. This can be avoided by careful laryngoscopic examination, determining the degree of inflammation in the tracheal mucosa before the injection is given, and regulating the strength of the remedy according to the indications.

The London *Lancet* of September 6, 1897, in an editorial review of an article of mine published in the *Journal of the American Medical Association* of June 26, 1897, speaks favorably of the method, but claims that it would be of no value in tuberculosis because the remedies will not reach the tubercular lesion. If this were a valid objection it would apply also to all remedies administered by the mouth. There is little blood-supply to the mass of tubercular infiltration, so that the chance of any remedy absorbed from the stomach acting favorably on the tubercular process through the blood is decidedly small. It is not claimed that tuberculosis itself can be arrested by tracheal injections, but many of the symptoms induced by the tubercular infiltration can be controlled by this method, without interfering with the nutrition of the patient, in a manner wholly unknown to those who use only the esophageal route for the introduction of remedies.

---

#### USE OF THE CURETTE.

---

BY MORDACAI PRICE, M.D.,  
Philadelphia, Pa.

---

There is probably no instrument now in use by the medical profession that has been so extensively and badly misused as the curette. It is used for the mildest uterine catarrh as well as for the most desperate hemorrhage in fibroid tumors—there is no mild, severe or intermediate condition to which the curette is not applied. There is

no condition of the pelvic organs so serious as to bar its use in the estimation of many in the profession.

The promiscuous and indiscriminate use of the curette has been the cause of more deaths than probably any other factor in gynecological surgery. Its strongest advocates are those who desire to be known in the community as operators—they are without the courage and experience to make them safe surgeons, yet they desire the reputation and large fees for doing something that should not be done. There is no operation in gynecological surgery that requires more knowledge of pathological conditions and a greater experience in the treatment of the diseases of women. To claim that any novice can select the proper cases for and successfully perform these operations is to deny the experience of the ablest men who have given this subject the most careful study.

Take any experienced pelvic surgeon, and with scarcely an exception he will speak of the contraindications to this operation, and urge the risks rather than the benefits of operative interference with the curette where there is involvement of the appendages or any intrapelvic inflammation.

How many men can decide as to the wisdom of this operation in any given case to their own satisfaction or the safety of the patient? In my own experience of thirty years, fifteen of which have been largely devoted to the treatment of diseases peculiar to women, I have found far more damage done in the use of this instrument than good. In fact, in my experience I have found forcible dilatation and curettement to be the direct cause of more abdominal sections for the removal of appendages than any other. The instrument should only be used after examination by and consultation with the most experienced men. The use of the instrument should only be at the suggestion of the most experienced and enlightened judgment.

It is common in inflammatory pelvic trouble to have a history like this: slight pain in the back with discharge from the vagina, sterile, anemic, nervous, and the consequent anxiety of the family. Then follows the history of treatment, which can be briefly summarized: The attending physician states that he has done all he can to cure leucorrhea and nervous symptoms. He then etherizes, dilates the cervix, and cures the womb; this he is always proud to claim he

did "thoroughly." She got no better—on the contrary all her symptoms became aggravated, with the additional symptoms of pain when walking and on defecation. He again curetted the womb, and from that time on her condition continued to grow worse—marked by chilly sensations and pelvic pain. The sequel of the treatment is the creation of a condition necessitating the castration of the woman.

It is grafting the consequences of an operation on an organ that had already reached the verge of all it could bear, and rough handling or mutilation, such as curetting, could only result in disaster. I will not occupy time in giving the conditions laid down for treatment by the curette, but confine myself to speaking only of those in which in my own experience I have found the curette of use. In endometritis it may be at very long intervals, in the practise of a very busy gynecologist, of use. I have never had to curette a half dozen cases of endometritis.

In fungoid growths of the womb, small or large polypus, and also in the fungoid forms of supposed malignant disease, where there is great loss of blood and the patient will not submit to extirpation, the curette is of great benefit.

I have seen marvelous results from thorough curetting and drainage. In many of these cases they lived on for years without symptoms of trouble. I will refer to a case in point, one in the practise of Dr. Shearer, of Sinking Springs, Pa. The case is one of a lady some forty years of age, a large fleshy woman. She began bleeding months before curettement, and at times there was very severe flooding. At the time I saw her, now over a year, the womb filled the entire pelvis—the mouth of the womb opened sufficiently to admit of a large-size sharp curette. She would not submit to a radical operation, so we decided to clean out the uterus. She was etherized, and the internal and external parts were thoroughly cleansed. With the first stroke of the curette large lumps of gelatinous material, brain-like in appearance, began to flow out—about half a pint of this material was rapidly removed, when the loss of blood was so tremendous that a yard of bichloride cheese-cloth was firmly packed into the womb, as the hemorrhage seemed in a fair way to prove fatal. In a few moments this was removed, when every vestige that could be found of the supposed cancerous material was curetted away and the womb again packed with gauze; a vaginal tampon

was also used, and the patient put to bed. It is now over a year since the operation was done, and Dr. Shearer informs me that she continues to improve and has had no return of her old symptoms.

In abortion, miscarriage, or after labor the curette has no place except in the grossly neglected cases where the woman has been allowed to go for weeks before the membranes and the placenta or parts of the placenta have been removed. All these cases should be treated promptly as soon as it is determined that the woman is aborting and the womb not able to throw off its contents. She should be thoroughly etherized, the hand introduced into the vagina, the finger or fingers into the womb, and every part of the membrane, placenta and clot removed. The fingers should be used; by sense of touch you can be absolutely sure that your operation is complete, while with the curette you may scratch and scrape and wound portions of the endometrium, thus opening new avenues for sepsis, and often the very part that should be removed is left.

I recall a recent case in which a physician curetted the uterus. A short time after he left the woman suffered from hemorrhage, and the family not being able to get the man who had performed the operation I was called, and when I reached the house the nurses showed me a three-months-old fetus that had just been passed. If a man could miss a three-months' fetus with the curette, might he not also miss some other things? With the fingers such an accident could not occur.

In long neglected cases the curette probably would require less violence than to attempt the removal of decomposing membranes and placenta by the fingers. I rarely see cases so neglected. In ninety-nine per cent. of the cases in which the curette is recommended or used I am satisfied the finger is the only safe instrument to use, but neither finger nor curette at any time without ether—an operation without ether is rarely satisfactory. The curette is of no use in ulcerative cancer, except it be used in connection with the cautery, where it is found to be a great benefit, in many instances relieving the patient for many months from the most distressing symptoms and giving comparative comfort.

In fibroid disease and myoma it is a useless and at times a dangerous procedure. You may take one hundred tumors removed by hysterotomy and open the uterine canal,

and you can wipe its lining clean with a cambric handkerchief, showing clearly that an instrument like the curette is not required. Many of these cases are tremendous bleeders. In doing these operations very few instruments are needed: a tooth forceps to steady the womb, a Sims speculum, and three sizes of curettes—the largest should be used without forcible dilatation.

It is understood that absolute cleanliness must be used both outside and inside the field of operation; if discharges are unhealthy, some antiseptic solution should be used.

Some advocate the shaving of the parts. If any one advocating this practise will first experiment with shaving his own private parts, after two weeks of the growth of the heavy stubble he will discontinue the horrible punishment of shaving in his operations. After cleansing the parts it is easy enough to cover them up with wet gauze during the operation.

Not a few men put forward the claim that they have never heard of bad results from the use of the curette. I have seen great numbers of them, and have offered a number of times when reporting such cases to give the name of the surgeon; the society declined to receive the necessary data to prove bad results, this possibly upon the ground that it involved the personal naming of some of the chief advocates of the procedure. Very many men do the operation because they think it is one they can do successfully; if the patient does not die the operation is reported as a success, no matter how aggravated the patient's condition may be. The little good that the curette has done in the cases where it is clearly indicated cannot begin to compensate for the terrible consequences of its abuse. We can only speak with any weight of authority when we speak from our own clinical experience and direct professional observation of the use of the curette. Statistics, as in other lines of surgical procedure, give us no reliable data upon which to base opinion. Every man puts the best face upon his report of cases. That this line of dealing with vital questions tends to the better enlightenment of the profession is questionable.

We get better lessons for our guidance from frank statements of facts as they occur in our experience than from reports of brilliant and uninterrupted successes, however encouraging they may be as to possibilities. From our mistakes and the recognized

errors of our procedures we gain lessons of safer guidance than many taught by our textbooks.

There is nothing in which our speech is so stammering as in admitting our mistakes. The rule should be: As little interference as practicable, and certainly no rough handling or blind cutting. If we are bothered with the number or weight of our instruments let us leave the curette at home.

*A STUDY OF THE DIAGNOSIS, ETIOLOGY  
AND TREATMENT OF TABES DORSALIS,  
WITH SPECIAL REFERENCE TO PRE-  
COCIOUS LOCOMOTOR ATAXIA  
AND THE ARGYLL-ROBERTSON  
SYMPTOM.\**

BY F. SAVARY PEARCE, M.D.,

Instructor in Physical Diagnosis, University of Pennsylvania;  
Physician to the Out-patient Department  
of St. Agnes Hospital.

In a study of 194 cases of locomotor ataxia I have noticed a number of odd relations of pupil affections, both as to time of appearance of ataxia and of irregularity of this sign. For this reason the writer began a research upon this subject. The notes from which this tabulation was made were so well taken in the majority of instances that jotting down interesting data from time to time made the study finally broader in its scope than was intended at the outset of the research.

It is with the kind permission of Drs. S. Weir Mitchell, Wharton Sinkler and Morris J. Lewis that I have been permitted to collate all the cases at the Orthopædic Hospital and Infirmary for Nervous Diseases reporting at the clinics up to date (many of whom received from time to time house treatment in addition). Some have been included in the paper on "Tendon Jerk and Muscle Jerk in Disease," by S. Weir Mitchell and Morris J. Lewis (*American Journal of the Medical Sciences*, N. S., vol. xcii, 363). The eye examinations were in most instances made or confirmed by Drs. de Schweinitz and A. G. Thomson. Dr. Chas. A. Oliver has also kindly placed notes of twenty-eight cases of tabes examined by him, taken from a collection of eighty-seven cases which this gentleman is compiling for a monograph upon the eye in locomotor ataxia. These latter are private cases and records of cases admitted to the Philadelphia Hospital nervous wards during 1895, 1896, 1897, and 1898.

*History.*—This disease has been known in a vague way since the time of Hippocrates, and more exactly since Romberg's description.†

*Definition.*—Tabes, tabes dorsalis, locomotor ataxia (Duchenne), or posterior sclerosis, is a degenerative disease of the posterior columns of the spinal cord or the peripheral sensory nerves, or both, and is manifested by considerable incoordination, Argyll-Robertson pupils, peculiar pains, and defective sensibility. There have been given varying significances by different observers to each. The name tabes dorsalis is to be preferred (as meaning wasting of the back, by the older observers, but as now histologically understood, a sclerosis of the posterior columns of the cord), on account of the fact also that incoordination may be absent in the incipency of the disease, and further that incoordination is not always found in the legs primarily, as has been reported by S. Weir Mitchell and others. Indeed, in the rarest instances incoordination is a meagre symptom of this system sclerosis.

*Etiology.*—Erb and Fournier lay great stress upon the syphilitic origin of tabes, and to this acquired dyscrasia undoubtedly the majority of cases can be placed (perhaps eighty per cent.). This must be due to specific spinal anemia, or to the syphilitic toxin poisoning the centers. Remembering, however, that when syphilis is the etiological factor, tabes is a remote consequence—a grandparent of the disorder (Mitchell)—one cannot hope to cure, or even more than stay the progress of the disease, even when known to be of specific origin.

Apparently mild syphilis seems more apt to produce locomotor ataxia, but we believe this is really not true, but rather that it is due to a determination of the specific disease to the central cord neurons; and hence, the laity statements of the disease "going in" being a bad omen really seems to have some foundation in fact.

Trauma, exposure to cold and wet, overwork and mental strain, are potent causes which should be given greater weight, as shown in our cases. Hereditary nerve disease does not seem to count much in causation. It takes some extraneous agent to induce this degeneration in most cases.

I am more inclined to think the immediate cause of the sclerosis is due in slow

\* Read before the State Medical Society of Pennsylvania, May 17, 1898.

† *Lehr. der Nerven Krankh.*, Berlin, 1851, p. 185; Sauvage's *Classica*, xi, 1.

forming cases, as said, to spinal anemia, the proportionately smaller vessels known to be in the posterior cord being affected by endarteritis, than that it is due to micro-organismal infection, as well as from the fact that hardening of the arteries (arteriosclerosis) begins in early middle life, the time for developing tabes. This theory is also substantiated by the fact that anterior poliomyelitis is an acute disease occurring in the young, and is situated in the anterior horns of the cord, where the vessels are proportionately larger. Also as infantile palsy most frequently develops in summer, as proven by Sinkler's statistics, very certainly it must be due to the micro-organisms' ready entrance into the anterior horns, for the anatomical reason given, and from the further fact that bacterial infection is more common in the heated season, when, too, the blood-vessels of entrance of the poison must be dilated *ad maximum*. We know more of this since the discovery by J. K. Mitchell that blood-corpuscles per cubic centimeter are increased enormously with varying causes (as massage), or no doubt with thermic conditions, or in varying barometric pressure and at different altitudes, in proof of which the writer has some interesting surface temperature records.

Therefore, as to posterior sclerosis, repeated congestions, either from cold or wet, or as would typically take place in malarial "chills," would cause congestion, subacute inflammation, occlusion of the smaller posterior column vessels, and the sclerotic anemia result.

The micro-organisms of well defined infectious diseases are not known to be causative of tabes dorsalis. Malarial poisoning, however, to my mind, must be more frequently a remote cause of tabes, producing the aforesaid conditions—spinal congestion, endarteritis—sequent anemia and sclerosis. To the toxin poison of the plasmodium we might also suspect a potent etiological factor for such sclerosis in malarial cachexia.

The accepted so-called easy immunity of the human body to these protozoa in the light of this may really be a mistaken conclusion. As with syphilis, it no doubt may start the same process of cord-congestion—endarteritis, anemia, sclerosis of the posterior columns. Rheumatism may act in the same way. Our tables show a sufficient number of cases of tabes following exposure to confirm this view. The trite saying of H. C. Wood in his lectures at the University, "Gentlemen,

when you have a difficult case of aberrant form, look to the trio of diseases—malaria, syphilis, or to rheumatism," can well apply to the etiology of many cases of tabes.

*Symptomatology.*—A syndrome in semeiology with cardinal points obtained in most of our cases—the incoordinate gait, fulgurant pains, the Argyll-Robertson pupil—but careful observation proves that this status is by no means as frequent as supposed. Then the stages—preataxic, ataxic, paralytic—are such relative terms as to be only a help in determining this from other simulating affections.

Undoubtedly in the present state of our knowledge, when we are able to diagnose tabes with difficulty, or ever so easily (from the correlated symptoms), the process must be even then histologically well advanced. It is with the idea of helping in early *diagnosis*, and therefore to most effective *treatment*, that I shall give some aberrant symptoms noted in the preataxic stage. According to Raymond, the better recognized incipient forms are: (1) the eye type, amaurotic; (2) the painful; (3) the gastric; (4) the articular type (arthropathies). Manifestly this relation depends upon the part of the nervous system first involved. Beyond this, or later in the course, coordination may be much delayed—*e. g.*, in the legs, where the disease is progressing higher up than the more usual thoraco-lumbar region.

Dr. A. G. Thomson and the writer have frequently observed together the aberrant forms at the Infirmary for Nervous Diseases, and have noted more especially two conditions, viz., where the history not infrequently is obtained that the eye symptoms long antedate the spinal, or *vice versa*. I feel sure the more careful attention as to this in the observation of our cases will be of great value in diagnosis, more in prognosis, and most in treatment. I have also felt that precocious cases, more constantly than the usual later developing forms, do not so often present the Argyll-Robertson sign, but do the Romberg symptom proportionately greater, as though the peripheral neurons were more affected in young persons and by wider spread lesions for the anatomico-physiological reason of vascular resiliency given. The Reber and Wilmarth theory\* of the explanation of the Argyll-Robertson pupil, as due to circulatory disturbance from occlusion of arteries in the

\**Transactions Medical Society of Pennsylvania*, 1896, vol. xxx.

finer vessels between the optic and oculo-motor centers seems plausible (likewise does an early occlusion of these fine vessels, together with the important factor of the length of the reflex arc, explain the early absence of knee-jerk); and this, I maintain, is the reason for less frequent Argyll-Robertson phenomenon in young persons. These more resilient vessels are not so quickly occluded from carrying nutriment to the eye centers.

Sudden onset of tabes is likewise less frequently associated with the Argyll-Robertson pupil, as though the cord were earlier affected than the oculo-motor center. I reported such a case before this society in 1896.\* When the pupil is involved in precocious cases, those we have observed have been more of inequality and of iridoplegia, the pupil being generally in myosis apparently due to irritation of the third nerves. Such a case of our series is typified in A. G., aged twenty-two, deaf from birth; no syphilis; first attacked with eye symptoms at nineteen, followed by meningo-myelitis, increased reflexes (ataxic paraplegia), with a resultant lessening of knee-jerks, very marked ataxia, pains, paresthesiæ, and other phenomena of tabes. In this case under treatment the knee-jerks have partially returned, and ataxia of the hands especially bettered. Movements were and are an important factor in the treatment of this precocious case. One of the two cases in our list, a colored man, of specific origin, has shown much improvement since being reported in my "Brown-Sequard"† paper before this society in 1896. We feel that round cell infiltration and less true sclerosis takes place in the black race.

So much has been written upon the classic forms of locomotor ataxia that it might seem repetition to say more, yet the consideration of the development of some of these unusual forms of the disease, it seems to me, opens up a new chapter in semeiology, in the careful study of which indications appear, and treatment may be the better directed towards staying the progress, especially of the acute cases. The importance of thoroughness of any therapeutics of the malady should be insisted upon and confidence of the patient gained by timely diplomatic forewarning of the nature of the disorder in order to secure

the best results. Then, too, if the sclerosis is not so happily checked, the pathological change in the posterior columns of the cord may occasionally be stayed, at least from advancing so rapidly, as we have seen by such guidance in some cases that were prior to conscientious adoption of systematized treatment making rapid strides for so chronic a disease as we know tabes to be. Aside from this, the relief of distressing symptoms can be frequently attained by simple methods pointed towards the rational understanding of the individual case—e.g., in the paper referred to last the value of testicular fluid injections in nineteen cases of ataxia (eleven of which were improved) was pointed out, as well as its use in other nervous affections. Since then, as pointed out in my conclusions of the record, the drug has proved its efficacy in a limited number of cases.

The following rare case, illustrating the precocious type of Duchenne's disease and with unusual etiology is here recorded: S. M. T., aged twenty-two years, of Irish-American parentage, reported for treatment at the clinic of the Orthopædic Hospital and Infirmary for Nervous Diseases in the service of Dr. S. Weir Mitchell, to whom I am indebted for the privilege of making this presentation. The patient's mother was said to be epileptic. He has three brothers and two sisters in splendid health, and there are no other nervous or diathetic maladies in his ancestry or among living relatives. The mumps and measles were the only diseases of childhood he had; never had any convulsive disorder. There is a vague history of stammering in childhood, soon recovered from. He grew to be a bright child and in every way apparently normal. Has never been a drinker, except occasionally of beer, and but periodically an excess of this, and there is absolute denial of syphilitic infection. No signs of specific disease can be determined. There is no history of metallic poisoning. He went to school until fourteen years of age, since which time he has been in the livery and later in the insurance business, at which for three years previous to the onset of the present trouble he walked excessively, as a collector—at times upon his feet eight hours daily. The onset of his disease he dates from December 16, 1895, when he was twenty years and three months of age, and immediately succeeding a severe attack of malaria, in which sweating, fever, a dull pain in the thighs, especially down the sciatic regions, violent vertical and frontal

\**Journal of Nervous and Mental Diseases*, January, 1895.

†A Clinical Report on the Use of Testicular Fluid Injections, *Transactions of the Medical Society of Pennsylvania*, vol. xxvii, pp. 165-179.

clavus-like headache with anorexia, were symptoms. There were no convulsions nor paralysis. He lay prostrate one week and was then taken home from his boarding-house, some thirty miles distant. One week later he was about again, but both legs now began to "jerk," and for that reason walking became difficult; it aggravated the condition so much that his gait became very unsteady, and soon he developed a sudden cardialgia upon such exertion as walking even a block. Then stiffness on rising in the morning became manifest and added to the annoyance of the subjective and objective "jerking" of his lower extremities. The precordial distress became rapidly worse on the slightest exertion.

Perhaps a month later lightning-like pains down the posterior aspects of thighs and legs became harassing and have continued intermittently ever since, in addition to which extreme fatigue in walking and the cardialgia crises mentioned were a triplet of etiological factors practically totally disabling our patient. He had no vertigo; bladder and bowel coordination remained normal. His vision was in no way disturbed, nor was the sexual function. There was no sensory disturbance developed other than the lightning pains noted.

Marked ataxic gait with increase of the above complex of symptoms had developed in a very short time—a few months—and has continued without abatement in spite of treatment (except as to some amelioration of pain), up to the time of coming under Dr. Mitchell's care, two years after the onset—*i.e.*, at twenty-two years—when we found the following:

*Status Præsens.*—Dark hair, nervous temperament, bright, 5 feet 3 inches in height, weight 125 pounds.

*Motor Symptoms.*—Station: Eyes open, unsteady; eyes shut, sways markedly in all directions. Gait is characteristic of locomotor ataxia. There is no static ataxia, and but slight associated movements of one hand when the other hand is tested for manner and range of motion.

*Sensory Symptoms.*—There is no loss of tactile, thermal or pain sense anywhere, but he still complains of intermittent, deep, lightning-like pains coming in paroxysms once or twice a week at their acme and located mainly in the postero-lateral aspect of the thighs, transitory and lasting from a few seconds to a minute. The pain is worse in damp weather, mere changes of atmospheric

temperature not affecting the pain one way or the other, nor does fatigue now seem to influence it. His rate of pain conduction is quick, power of localizing good, and weight sense preserved. There are no hyperæsthetic areas, but he complains some of paresthesiæ of the extremities. He has no "girdle" sensation, marked gastric or other crises, the cardiac attacks having abated.

*Reflexes.*—Plantar, tardy response. The gluteal, abdominal and other skin reflexes are normal. Knee-jerks are both absent and not reenforcible. There is no tendo Achilles jerk, nor ankle clonus. The elbow-jerks and muscle-jerks are preserved. There is no localized or general atrophy and no loss of weight. Dynamometer records R. 145, L. 130. Hearing is normal.

*Eyes.*—Pupils equal, normal size, and respond normally to light and distance; disks normal.

Bladder and rectum are continent. There are no vasomotor or antedating trophic phenomena, but since childhood the man has been able to voluntarily dislocate his left hip.

The patient's speech is thick and clumsy. There is no true aphasia. Deglutition is easy. Respirations are hurried but normal, 22 per minute. Heart sounds are rhythmic and average 78 to 95 beats per minute; pulse is rather feeble. There is no cardiac murmur. Bowels are regular; urinalysis negative. He had no fever or other evidence of suffering from malaria when reporting for treatment.

The patient was admitted to the hospital, and placed at absolute rest in bed, two weeks after his case had been treated with little avail as an out-patient. The "rest" relieved him of much of the pain, and he was further buoyed up much by testicular fluid injections. Daily scientific massage was practised, and after several weeks he was gradually gotten out of bed and was trained in gymnastic movements, as forward extreme flexion of the body, standing with his eyes closed, and in standing upon one foot with open and then with closed eyes, extensions of the arms over the head, and in training his incoordinate finger movements by voluntary daily practise. At the end of seven weeks his pain had disappeared, coordination was much improved, and he could jump from a street car in motion, something he had been unable to do for months.

When the patient was discharged from the hospital, on November 14, 1897, he was instructed to be on his feet but little and to

continue the gymnastic and flexion movements described in order to reeducate his disabled centers in coordination, a treatment which, begun here and abroad, has in our hands proved of value in several cases of ataxia. On February 18, 1898, the patient returned to the city, reported continued improvement, and appeared to be in excellent health. There is no notable difference in his nervous system, except that the exterior reflexes of the arms are more marked than the flexors, the elbow-jerks being very difficult to elicit. Coordination of hands had improved, however.

On March 4, 1898, he reported again. His station had become much more stable, and gait less ataxic. Pain in the left hip had become an annoyance, and during the past ten days that joint had become more easily dislocated. Stretching of the ligaments in a slip while walking may account for both. The elbow-jerks could not be elicited on this day, but the extensor response to a blow was quite normal. Perhaps the defect of speech had become more staccato. No advance in subjective sensations to patient had occurred; in fact, he was much improved in every way. The shooting pain down the thighs he had had for two years since the onset of the disease and his admission to the hospital had entirely ceased since his discharge; also the occasional irregular vertico-lateral shaking of the head, which he now told us bothered him some before admission, had likewise disappeared. He said he was stronger in his arms and could drive a team of spirited horses with certainty and wished to know if he could ride horseback, which was, with some misgivings, granted; the training in such, of course, being one of the best for coordination, as they well know who ride.

On April 12, 1898, the patient was seen again and showed improvement as to head shaking and ataxia. The training was ordered continued.

This case illustrates one of early aberrant ataxia with absence of the Argyll-Robertson symptom, with absence also of marked crises and girdle sense, and with a history of acute malarial intoxication as the probable exciting etiological factor, admitting that such precocious idiopathic predisposition may have existed. It has stimulated search of the literature and this study of a large number of cases, but no instance of malarial poisoning has been found positively recorded as causative of tabes. I think it must be an overlooked but rare etiological factor.

The following tables have been compiled and will suffice to more thoroughly illustrate prominent symptoms present in the cases here analyzed, the indications for treatment of the patients heretofore referred to, and the systematic management of all cases of tabes dorsalis:

TABLE I.—TABULATION OF 194 CASES TABES DORSALIS.  
(F. Savary Pearce.)

\* 44 not given.

† 37 not given.

Cause given (112 cases): Smoking (tobacco), 2 cases; alcoholism, 10 cases; exposure to wet and cold, 50 cases; grippe, 4 cases; trauma, 3 cases; bleeding piles and operation for, 3 cases (confirms our opinion as to anemia of cord being ultimate chief cause of tabes; primary cause varies); syphilis only, 15 (?) cases; rheumatism, 25 cases.

Cause found (in some not determinable): La grippe, 2 cases; alcohol, post-alcoholic neuritis, 12 cases; trauma (back, etc.), 16 cases; gunshot wound, 4 cases; idiopathic congestion of cord, 2 cases; malaria, 1 case, possible 2 cases; idiopathic, 16 cases; lead poisoning, 4 cases; acquired syphilis traced positively, 29 cases—1 in 6 cases; number cases of congenital specific taint noted, 3 cases; exposure to wet and cold, 5 cases; overwork (strain) and worry, 20 cases—1 in 9; hereditary nervous diseases, 5 instances; insanity alone, 1 instance; complicated by general paresis, 2 cases, both males; paralytic stage, 1 male, 1 female.

Average time after initial lesion of syphilis, 24 years (fourth stage syphilis).

TABLE II.

Males, 166; females, 28; proportion of 6 to 1. Eulenburg reports 128 to 21; proportion of 6 to 1. Gowers reports 10 to 1. Duchenne saw only four cases, and Trousseau only three cases, of tabes in women. Dr. S. Weir Mitchell tells me he has seen 24 cases.

Nationality: American or English, 119 cases; French, 2; German, 21; Hebrew, 6; Irish, 25; colored (not pure), 2. In nineteen cases the nationality is not given.

Aberrant forms: Six cases. Pseudo cases, 16; phthisis (?) in 16 cases.

Motor phenomena: Tremor marked in 4 cases; paresis of all muscles early, 17. Paralytic form (stage), 2 cases. Most cases able to be (walk) about.

Sensory phenomena: Anesthesias noted in 12 cases; paresthesia in 125 cases; pain, 13 cases. Location of marked pain mostly in stomach, next in legs, less in arms. Rare crises, laryngeal, 2 cases.

Knee-jerks slightly persisting, 3 cases.

Eyes: Atrophy, 30 cases. Argyll-Robertson pupil, 150 out of the 156 in which this symptom was carefully noted, and less in young cases.

Blood average of half a dozen anemic cases; hemoglobin, 45 per cent.; red blood-corpuscles, 2,464,000.

Arthropathies: Seven cases. Amaurotic type, 4 cases; heart and circulation, 2 well marked aortic murmurs; 4 systolic mitral murmurs. Skin cold in most cases. Pulse above 98. In 7 cases pulse over 100 constantly.

**Diagnosis.**—Diagnosis must be made from spinal syphilis, which is an early tertiary lesion (tabes might be called a *quaternary* stage or lesion), by noting the more early involvement of the bladder in syphilis of the cord, the more wide-spread lesion, and the, as a rule, more irregular symptoms, as of the pupil phenomena and the shifting nature of the disorder. Generally the irritation of the lateral tracts in syphilis of the cord is sufficient to produce spastic knee-jerks.

In Friedreich's disease, from the very early development, the nystagmus, the lateral curve of the spine, the club-feet, the staccato speech, make differentiation easy.

From polyneuritis (many of the pseudo-cases) great difficulty is sometimes experienced. Look for tenderness of the nerve trunks, atrophy and reactions of degeneration, some reenforced knee-jerks varying in degree of response, normal pupils, and more quick response to treatment. One of our cases was so typical of tabes as to make diagnosis not positive until a somewhat rapid cure followed treatment. It is to be remarked that la grippe the past winter has been a potent cause of neuritis, taking on, too, this peculiar pseudo-tabetic type.

From cerebellar lesion, the titubation, aural symptoms, more constant objective vertigo, shifting knee response, and associated hysterical phenomena should not mislead.

Hysteria can mimic anything. The knee-jerk is almost never absent *in toto* in hysteria, nor would a suspicious Argyll-Robertson pupil be found to be *bona fide* upon repeated examination.

Hypnotism or etherization may be required to distinguish between hysterical ataxia and true tabes in rare cases, for marked ataxia and even crises may exist in hysteria; yet the shifting condition of symptoms in hysteria would be points. Of course, stigmata of hysteria are to be looked for, and on the other hand the greatest blunders are made when one disregards organic disease, hysteria also existing. S. Weir Mitchell and J. H. Lloyd have reported interesting cases of hysterical ataxia. Patches of anesthesia about the trunk and thighs have been especially noted by Patrick and others.

Pernicious anemia may go on to tabes.

Several cases in this series have been reported by Wharton Sinkler and Eshner; while Burr has made confirmatory histological examinations in these cases.

**Prognosis.**—The average life of tabetic patients is from ten to fifteen, or even fifty years. No one can foretell the power of resistance of the individual. Taken all in all, an early case (as in epilepsy) tends to be worse, for the reason of susceptibility of all tissues, and to wide-spread invasion in the young, as previously referred to in the early part of this contribution.

Complications of tabes are asphyxia or syncope, of central origin, phthisis, paralysis of the bladder, or septic cystitis and septicemia, tormenting pain, and finally general paralysis, really the terminal stage of the disease. Incidentally it may be mentioned that the voluntary attempt at deep inspiration for better oxygenation of the blood (sighing) is an endeavor of Nature to reenforce the weakened vagi and phrenic nerve centers.

**Treatment** is a long and careful business. By studying the etiology and symptomatology most carefully and minutely are the best results to be attained. I am more hopeful than most therapists, but believe, however, with Collins, that syphilis once contracted and thoroughly treated may still leave behind the "something" that causes degeneration of the posterior columns. In the unsuspected case (where the syphilis was thought entirely eradicated years before), then, if a sequent tabes does begin, it is most apt to be very incipient and perplexing in diagnosis. I have seen such a private case in the practise of Dr. S. Weir Mitchell, where most thorough antisiphilic treatment had been carried out by competent men, but the specific tabes, confusing as it was, was surely coming.

Treat syphilis thoroughly. Keep up the general health of the patient in suspected tabes. At all hazards look to the stomach; treat any rheumatic or any other diathesis; continue small doses of iodide of potash and bichloride of mercury, which are valuable alterative adjuncts in most cases from any cause. Cod-liver oil is the nutrient *par excellence*. Diet is paramount and should be suitable to the individual case (a most nutritious one). Donovan's solution gtt. v to x t. d., auri et sodii chlor. gr.  $\frac{1}{8}$ – $\frac{1}{4}$ , sometimes act wonderfully well as alteratives. Antipyrin and phenacetin are the most valued of analgesics, but heart and circulatory depression, which I have seen disastrous in several instances of painful tabes, should be

guarded against. Use morphine only as a *dernier ressort*, else you add to tabes another almost as serious a malady, we can almost say. The phosphates and testicular fluid injections have been proven of value to aid nerve nutrition.

Suspension by the Mitchell or Lombard apparatus (head-elbow) has been fully reported on by Hinsdale, with beneficial effects in some cases. This is probably due to stretching the membranes of the cord, freeing the posterior roots, and hastening circulation in the posterior columns.

The training of coordination, also used at the Infirmary for Nervous Diseases for the past twelve years, consisting of having the patient stand with eyes open, then closed, approaching the fingers to the nose, etc., under these two conditions, and also walking upon a straight line, of flexions of the limbs and trunk and training of static coordination (a treatment recently elaborated by Frankel), I have seen do great good, as evidenced by a case reported by me in the *University Magazine* for May, 1898. The more extreme gymnastic measures should be used in the order of strength of the patient—*i.e.*, whether he is in the incipient, the ataxic, or paralytic stages.

Cauterization of the spine may much alleviate pain. Bromides may occasionally be required to allay irritability of the nervous system. Strychnine is apt to do harm, but small doses of nux vomica may do good in toning up the digestive tract. Keep the bowels well open, and the urine normal by diuretics.

Electricity in the form of faradism and descending galvanism and franklinization are in this order agents of value not frequently enough scientifically used. Hydrotherapy has an important rôle—hot and cold baths. Hydrotherapeutics in the shape of hot and cold douches applied to the spine especially for five minutes daily is often of great stimulating power.

A rest treatment may be essential for the best results in a stubborn advancing case. Such patients should never exercise to tire, and should be in the fresh, dry air much, especially at high altitudes, thus to favor peripheral circulation by decreased pressure. Massage and electricity properly applied, as said, are most valuable. The use of stimulating liniment rubbed well over the surface of the body has proved also of great value in stimulating circulation, so deficient in this class of patients.

The following prescription has done well in my hands:

℞ Ammon. chlor., ʒ iij;  
Glycerin, f ʒ j;  
Tr. capsic., f ʒ ss;  
Aq. menth. pip., q. s. ad f ʒ xij.

M. et sig.: Rub on body daily for twenty minutes, with the massage.

#### ERYTHEMATOUS RASHES FOLLOWING THE USE OF ENEMATA.

BY RAYMOND CRAWFORD, M.A., M.D. OXON., M.R.C.P.  
LOND.,

Assistant Physician to the Royal Free Hospital, and to the  
Victoria Hospital for Children, London.

From time to time the subject of scarlatinal and urticarial rashes appearing after enemata crops up in the medical papers, and is regarded as somewhat of a rarity, the fact being that they are extremely common. It is surprising that in the chief medical textbooks there should be no authoritative recognition of the phenomenon. If this association were kept in mind, a deal of light would be thrown on many of the unexplained rashes that alarm and puzzle house physicians. During my own period as house physician I made brief notes of fourteen such cases, and several more were not recorded as soon as we were assured of their causation. The rash invariably occurred in young patients, the eldest of these fourteen cases being a girl of sixteen. Of this group of cases nine were girls and five were boys. It was not in every case associated with constipation, as in two cases it followed half-pint injections of salt and water into the rectum for the expulsion of threadworms. Of the remaining cases five were suffering with or convalescent from typhoid fever, three were cases of chlorosis, one a case of gastric ulcer, one a case of inflammatory trouble about the sigmoid, and the remaining two were in children prior to operation. There was thus a marked association with gastro-intestinal disorder, and constipation was only certainly absent in two of the cases. However, it must be borne in mind that these are the very cases in which in the nature of things enemata will most probably be used.

It is difficult to say how soon after the injection the rash appeared, as it was often not noticed until the patient was washed, its common site of origin in our cases being the buttocks. In one or two cases it appeared within three hours of the enema. In the milder cases the rash was usually scarlatinal in character and diffuse, but in more

severe cases confluent, and occasionally urticarial. There was no absolute uniformity of distribution in the cases, though the localization was to some extent a diagnostic feature. It was symmetrical, usually most marked upon the buttocks, and spreading downwards over the thighs front and back to the knees; in an upward direction it commonly extended as high as the angle of the scapula, and tended to be thicker over the flanks than over the abdomen. The arms, above and below the elbows, were affected, but not so constantly as the legs. Only in five of these cases was the face affected, and then the distribution was pretty general over the forehead, ears, cheeks, and on the neck, particularly along the line of the lower jaw.

There was nearly always some degree of irritation of the rash, not marked in the scarlatinal cases, but often intense in the urticarial cases. In one or two cases there was no complaint throughout. The rash usually subsided in less than twenty-four hours from the time of being first noticed, but in one case an urticarial rash persisted through three whole days. In none of these cases was the rash followed by desquamation.

In all but two cases the initial enemata were of soap and water. In two cases I was anxious to see whether the soap was to blame, and tried plain water enemata instead. In one case no rash followed the enema, neither did any rash follow the repetition of the soap and water enema. In another case—a boy with inflammatory trouble around the sigmoid—we were able to prove to demonstration the connection of the rash and the enema, by producing a rash whenever an enema was administered, and this indifferently as to whether the enema was of water or soap and water. I have never seen a rash follow the use of a glycerin enema, or a glycerin suppository; the same, too, is true of nutrient enemata, the bowel, however, in these cases having always first been cleaned of feces by a soap and water enema.

In only one of these fourteen cases was there any soreness of the throat, and this was not of a degree to suggest scarlet fever. In four of the cases there was a rise of temperature coincident with the rash, but in each case below 102°; in five there was no alteration of the normal temperature; and of the others I have no record.

It has been suggested that the eruption is due to the sudden absorption into the blood and lymph streams of poisons from feces accumulated in the intestine; while dry they

are harmless, but wet them and absorption commences at once. As is the case with other irritants in the alimentary canal, their entry into the circulation is often exhibited as a sharp attack of urticaria. The greater frequency, or perhaps one may say the exclusive incidence, on children is merely an index of a more delicate skin. If such be the explanation one would naturally expect to find similar eruptions occurring after purgatives, especially those that, while failing to produce an evacuation, serve to liquefy the feces in the intestine. However, it is quite intelligible that such may not be the case, when one recalls what marked relief of the so-called toxic symptoms of an ordinary constipation follows the administration of a laxative, even though there be no actual passage of feces. A recent writer in the *British Medical Journal* asserts that such rashes are occasionally associated with brisk aperients.

The whole importance of these rashes consists in the recognition of their cause, so that they may not be mistaken for aberrant cases of scarlet fever, and this can be best effected by remembering the association. In themselves they are of no importance, as they subside spontaneously with the simplest attention to the function of the gastro-intestinal tract.

**REMOVAL OF THE OVARIES AND TUBES;  
REMOVAL OF OVARIES; CHRONIC  
OVARITIS PRODUCING RE-  
FLEX DISEASE OF  
THE EYES.\***

---

By E. E. MONTGOMERY, M.D.,  
Professor of Clinical Gynecology in the Jefferson Medical  
College; Gynecologist to the Jefferson and St. Joseph's  
Hospitals; President Philadelphia Obstetrical  
Society; Ex-President Pennsylvania  
State Medical Society.

---

Owing to an attack of sickness I have not been able to see until now the patient whom I bring before you. She is under an anesthetic, and we will first carefully examine and determine her condition before we decide as to what we shall do. We are prepared for operation.

The patient is twenty-five years of age; her mother, father, two sisters and a brother are living and well. She had the ordinary diseases of childhood, and typhoid fever. She menstruated at seventeen, the flow being scant and attended with severe pain. Shortly after the advent of menstruation it ceased

---

\*Clinical lecture delivered at the Jefferson Hospital, before the American Medical Association.

and did not reappear for a year. She then had trouble with her lungs, with cough and considerable expectoration. She was treated for tuberculosis. She informs us she had scrofula when young. After treatment her menstrual function returned, but has been more or less irregular since. She was married at twenty-two, but has never been pregnant. At present she has constant dull pain in the left ovarian region. This pain is aggravated at times, and becomes very severe on exertion. After exercise she swells, and this continues until the entire abdomen is distended. On several of these occasions she has been suspected of being pregnant, and about to suffer a miscarriage. The condition passes away with a discharge of a large quantity of gas. She has suffered much from headache, particularly in the back and front of the head. She informs us she has of late lost flesh rapidly. Her appetite is irregular, and bowels constipated. Any attempt to regulate the bowels results in diarrhea; pain also upon their movement. There is burning pain during micturition, and constant leucorrhea. Of course, some of these symptoms indicate the neurotic character of the disease.

Whether it would be necessary to do any operation on this patient will entirely depend upon whether we find organic change. I would not for one moment consider it advisable to remove the ovaries simply because she has such attacks, but limit such an operation to diseased conditions which can be determined prior to the procedure.

On examination we find there is a mass on the left side of considerable size. It is evidently not intestinal; that it is by no possibility a phantom tumor is evident from the fact that she is under an anesthetic, which would at once bring about its subsidence. There is some enlargement of the ovary and tube on the right side, but much less than on the left. The mass is situated so high on the left that I do not feel it wise to undertake the operation through the vagina, so I will make an abdominal incision.

Remember the history of this patient, the history of scrofula in early life and the treatment she has undergone for suspected tubercular disease. It is not impossible that we may have tubercular disease of the ovary and tube on the left side. She has been married a number of years and never been pregnant—undoubtedly, then, the result of conditions which have produced changes in the ovaries and tubes that have rendered her sterile. Of course she may have had an

infection which may have produced an inflammation extending into the pelvis, but the early history of the patient would rather lead us to believe that the trouble is independent of any infection of this kind.

I cut through the abdominal wall into the peritoneal cavity and find a cyst over the fundus of the uterus which ruptures easily; everything is matted together. The cyst is evidently one of the corresponding ovary and tube. The pedicle is separated, drawn out, and transfixed with silk, using as fine silk as will serve the purpose for its ligation. I generally prefer chromicized catgut for this purpose, as it is absorbed, and when absorbed we are not subsequently troubled with it. The entire omentum is forming a part of the mass which we have felt. The cyst ruptures as soon as it is touched. I now bring up the right ovary and tube, and I will show you that it is also in a condition which precludes its ever being functionally useful, so you can see why she has never given birth to children. Here is the tube, the end of which is closed; there it is united with a cyst of the ovary.

In this case the end of the tube has been bound down to the surface of the ovary by adhesions and fluid accumulated within the tubal canal, a cyst developing in the ovary at this point, the wall of which has subsequently through pressure broken down, forming a continuous cavity—thus, a tubo-ovarian cyst. This ovary and tube is removed. Ordinarily in such a case I would advise removal of the fundus of the uterus, when it is necessary to remove both ovaries, but in this patient the uterus is small, and I do not see that the additional operation is necessary.

The very important point in these operations is to make sure of complete hemostasis. I look at both stumps here to make sure that hemorrhage is completely controlled. As there is no bleeding we proceed to irrigate the cavity with a normal salt solution. This fluid as it flows out is bloody from the cyst which ruptured on the left side. We find there has been bleeding below the point at which the ligature was applied from some adhesions, and we apply the ligature further out on the pedicle. We fill up the belly with a normal salt solution and close the wound. This serves the same purpose as hypodermoclysis. The wound is closed with a Haughey suture, which consists of a continuous suture for peritoneum, muscle, aponeurosis, and subcuticular for the skin, the ends of each suture being brought out at the ends of

the wound and secured by perforated shot over perforated plates. This suture secures thorough apposition of the aponeurosis and thus firmer union.

*Removal of Ovaries; Chronic Ovaritis Producing Reflex Disease of the Eyes.*—The next patient is thirty-one years of age, whose mother is living and healthy. Her father died of typhoid fever at thirty-eight, one sister died of tetanus at thirty-six, four brothers died in infancy, and one is living and healthy. She had the usual diseases of childhood, with puberty at thirteen, regular periods, flow scant, accompanied by severe pain. She was married at nineteen and had one living child thirteen months subsequently, delivered by instruments; suffered a miscarriage five and one-half years later. During the birth of her child the cervix was lacerated; had an operation in November last. This relieved her of the bearing-down pain, from which she constantly suffered, but she still continued to have pain in the back, interrupted in character, worse at night, very severe during menstruation, of a dull aching character over the situation of the left ovary. Occasionally there is pain on the right side. She complains of a peculiar drawing pain in the back of the neck and shoulders during the menstrual periods; no discharge, appetite fair, tongue clean, bowels regular. She has been treated in the out-patient ophthalmological department, and was referred from there to this ward.

The eye trouble began last August, and has grown gradually worse. At present she can scarcely see to read or sew. Ocular conjunctiva very painful, cornua hazy, and there is a marked pericorneal injection. The patient denies any syphilitic lesion, but states she has had repeated eruption over the body, hair constantly falling out, and suffers with sores and occasionally pains throughout the body. The diseased condition of the eyes has been attributed by the ophthalmologist to reflex conditions. The symptoms have not subsided under ordinary methods of treatment, and this form of condition is frequently the result of uterine disease.

Upon examination we find she has retroversion of the uterus, and the organ bound down. Upon the hasty examination I made of the patient a few minutes ago in the ward I was unable to determine any enlargement of the ovaries. Looking into this pelvis you see the absence of the fundus of the uterus where we normally expect to see it, lying forward. I push the intestines back and you

now see the fundus of the uterus; in other words, it is lying low in the pelvis. Now, looking in, you see the fundus, which has been raised up and turned forward. In the left ovary is a cyst, not very much enlarged, which I open, peel out the cyst, and find another in the right ovary. We have taken out the diseased portion of the left ovary and saved the structure. We close the ovarian wound with catgut.

The right ovary is found even worse than the left; part of this organ is in a diseased condition of ovarian apoplexy. We resect the diseased portion here and bring the parts together with suture. This may seem like a small part of ovary to leave, but I have seen a child secured on a smaller amount, and it is worth preserving. I have to be more careful in securing this on account of the possibility of hemorrhage. This is one of the large ovarian branches. We pass a ligature through the base on one side, in that way cutting off the blood-supply and arresting the bleeding.

I propose to fasten the fundus of this uterus to the peritoneum by the suture through the summit of the fundus, and a second suture a little farther back. The reason I do not take more than the peritoneum is that if the muscular was included we would have firm bands of adhesion which, if she subsequently became pregnant, would interfere with gestation and parturition; but the peritoneum stretches and forms a loose band that permits the uterus to move about and still stays the organ forward. I made no haste in this operation, because I wanted to show you its different steps and give you an opportunity to see how it is done. We close this wound with the Haughey suture in the different layers.

#### THE TREATMENT OF CHRONIC RENAL DISEASE.\*

BY NESTOR TIRARD, M.D. (Lond.), F.R.C.P.,  
Physician to King's College Hospital and to the Evelina  
Hospital for Sick Children.

In discussing the treatment of chronic renal disease it is necessary to commence by some subdivision of the subject further than that indicated in the official programme, since the treatment of chronic renal disease includes several conditions which differ in their pathology and symptoms quite as much as in their etiology. For the purposes of the

\* A paper read before the British Medical Association at Edinburgh, 1898.

present discussion it may be convenient to divide the subject of chronic renal disease according to broad pathological lines under the headings of chronic nephritis, renal cirrhosis, and lardaceous disease.

The first condition is that which includes chronic forms of renal disease which are commonly consecutive to an acute attack and the changes are partly connected with the glomerulus, partly with the tubules of the renal epithelium, and partly with the interstitial tissue. The principal changes, however, affect the two former structures.

With renal cirrhosis we are dealing with a disease of perhaps more chronic type which commences very insidiously, taking its origin in irritation due to alcohol, to gout, or to other forms of chronic irritation. In these the interstitial tissue is chiefly affected by an overgrowth at the expense of the secreting structures, and in this condition, also, the vascular system is greatly altered, the left ventricle is hypertrophied, the apex beat displaced, the arteries thickened, and the blood-pressure raised.

In the third, lardaceous disease, the capillary tufts and the small arteries are primarily affected, but it is rare for this condition to exist without some interstitial changes, and inasmuch as lardaceous disease commonly results from some chronic suppurative process, the symptoms are those of the original disease rather than of renal affection.

Taking these three types, then—chronic nephritis, renal cirrhosis, and lardaceous disease—the subject calling for discussion is the treatment applicable to these various conditions, and since the last mentioned plays such a secondary part and since the treatment is necessarily almost entirely restricted to the surgical treatment of the primary cause, it will perhaps be more convenient to limit attention to chronic nephritis and to renal cirrhosis. Of these two conditions there is much room for discussion concerning hygiene and diet. Can we, by any hygienic change, or by any dietetic directions, modify the course of these conditions? Can we, by these means, retard the disease, or is it possible to exert any curative effects? Or, on the other hand, are our efforts in these directions to be limited solely to the relief of prominent symptoms as they arise?

In chronic nephritis there is a tendency to the occurrence of subacute attacks with small provocation. Patients who have been passing a fairly large amount of albumen in

urine of almost normal specific gravity may, from time to time, pass blood, and the appearance of the urine might, in the absence of history, lead to a diagnosis of acute nephritis. These subacute attacks during the early stages of chronic nephritis form, perhaps, the greatest danger to which these patients are liable, since there is fair reason for believing that such attacks indicate an extension of the disease to some portion of the kidney which was previously but little affected. Hygienic treatment, therefore, has largely to be directed towards diminishing the risk and frequency of these subacute attacks, and there is very little doubt that these risks may be diminished by the avoidance of exposure to sudden alterations of temperature; and if the means of the patient do not permit him to change his occupation, or to winter abroad so as to avoid the proverbial uncertainties of the British climate, much may be done by clothing in non-conductors which readily absorb moisture and from which evaporation proceeds slowly. Such non-conductors are of course to be found in various forms of woollen garments, and while it is advisable that patients should be thoroughly clad in wool, it is especially advisable that they should wear a broad flannel binder round the waist similar to the woollen "cholera belt" of tropical countries. Precautions of a like character may sometimes also be taken in connection with cases of renal cirrhosis, but the occurrence of subacute attacks is less to be feared since it is less frequent.

The prejudicial influence of overexertion and of mental strain is likely to be felt in connection with both of these types of chronic renal disease, and it therefore becomes necessary to recommend that patients should, so far as possible, guard against business anxieties and worries, and against late hours and other forms of excess. In both conditions, however, it is undesirable that the patient should be encouraged to lead a life of idleness, since one of the most troublesome features connected with chronic renal disease is the tendency to mental depression. In both conditions moderate exercise is likely to be beneficial during the early stages, and with renal cirrhosis, where the drain of albumen is comparatively small, the progress of the disease may be delayed considerably by judicious outdoor exercise. I have known one case of renal cirrhosis which has remained almost stationary during the last twenty years, the patient being so placed that he was able to indulge in golf, in cricket,

and in hunting, while of more serious work he was able to undertake the duties of justice of the peace and also to interest himself in local politics.

The problems concerning the dietary of chronic renal disease do not, I think, leave much room for difference of opinion. It is possible to prejudice the well-being of the patient by undue restrictions as much as by too great liberality. It is undoubtedly possible, by carelessness, to increase the amount of albumen lost in chronic nephritis; and, on the other hand, it is possible to weaken the patient materially by persisting with a dietary containing but few albuminous articles.

Chronic nephritis probably calls for greater care than renal cirrhosis, since the drain of albumen is greater and since also carelessness, more particularly with regard to alcohol, is liable to favor the supervention of the subacute attacks. During the occurrence of a subacute attack the dietary of the patient has to resemble that ordinarily adopted during acute nephritis, but after the disappearance of blood and after the albumen appears to have reached a fairly constant stage, there is no advantage in persisting in a non-albuminous form of diet; and, on the other hand, there may be considerable disadvantage in endeavoring to force the patient to persist with a distasteful dietary of milk and beef tea to the exclusion of solids. From time to time it has been held that in cases of chronic nephritis albuminous substances in the dietary should be reduced in quantity from the dread that they might increase the loss of albumen, and experiments have been made with a view to showing that, for example, the consumption of eggs is likely to be followed by an increased loss of albumen. It is, of course, somewhat difficult to estimate whether the increased loss bears any definite ratio to the increased consumption of albuminous substances, but inasmuch as the well-being of the patient depends, not upon the amount of albumen lost, but upon whether the loss is greater than the gain, it will be evident that in determining whether albuminoids such as eggs and meat should be given we have to be guided by the effect upon the strength and comfort of the patient. The foregoing is, however, only true during the early stages of chronic nephritis, and it is generally admitted that as the disease progresses and as the tendency to dropsical effusion becomes more marked the diet has to be modified somewhat, so that larger quantities of bland, unirritating fluids have to be taken with the

view of increasing the eliminative work of the kidney.

In considering the dietary of patients with chronic nephritis or with renal cirrhosis it must not, however, be forgotten that in both conditions there is extreme probability of dyspeptic disturbance, and the dietary of the individual has, to a great extent, to be modified in accordance with this danger. On the other hand, it must not be forgotten that dyspeptic disturbance in both of these conditions may form indications of the onset of uremic symptoms, and it has even been suggested that this might result from a dropsical condition of the mucous membrane of the stomach and the intestine in cases of chronic nephritis. This tendency to dyspepsia generally leads patients to have some aversion to many forms of diet; in particular they frequently rebel against meat, and accordingly it is generally desirable almost entirely to eliminate ordinary butcher's meat from the dietary so that the tendency to anorexia is minimized. Similarly it is usually advisable to encourage these patients to take a fairly large proportion of milk, though not to enforce a milk diet. Milk appears to stimulate the kidneys slightly and to promote the removal of nitrogenous waste. Frequently, however, it is found to be too constipating in its effects and to necessitate the occasional employment of some mild laxative.

While it is possible to favor the extension of chronic nephritis by excesses with alcohol, we are often asked whether alcohol should be taken at all by these patients, and if so in what form, and in what amount. The use of alcohol will probably leave room for much difference of opinion, and I fully anticipate that the course of the discussion will, to some extent, turn on this question. My own feeling is that it is generally better not to interfere with the ordinary habits of the individual with regard to alcohol, provided these habits do not lead to excessive consumption of stimulants. I would defend my practise by a reference to the well known depression of spirits and lack of appetite so frequently shown by patients with chronic nephritis. As in delirium tremens, it will often be found that small quantities of alcohol will enable food to be taken even when the appetite and digestive powers appear to be at a low ebb; and on the other hand, in these patients total abstinence is likely to be followed by severe depression, which is not only a source of discomfort to the patient and his friends but also a source of weak-

ness. As to the form of alcohol I think it is better to avoid the use of malt liquors, though small quantities of bitter beer seem to do very little harm, unless the patient is suffering from renal cirrhosis of a gouty type. More commonly one is in the habit of encouraging patients of middle age to take at meal-times small quantities of pure spirit well diluted. I lay some stress upon the need of purity since, in these cases, the spirit that is permitted is used as a drug which is intended to counteract depression and to assist digestion, and inferior forms of spirit are only too likely to increase the tendency to headache of which these patients so frequently complain. From the foregoing remarks it will be seen that I think that when chronic nephritis or renal cirrhosis exist the dietary has to be planned so as to avoid further extension of the disease, and that the utmost that can be hoped for is to arrest rather than to cure.

*Medicinal Treatment.*—The medicinal treatment of chronic nephritis is not very hopeful, and the attention is confined almost entirely to the treatment of various symptoms which develop in the course of the disease. When there is reason to believe that the disease results from malaria or syphilis, the ordinary treatment adapted for these diseases may be employed. Efforts have been made from time to time to relieve the inflammatory condition which has been found to continue during the greater course of chronic nephritis. Various astringents have been used with the view of controlling inflammatory action, while tartar emetic and nitric acid have been recommended for the same purpose. It is much more hopeful, perhaps, to consider the symptomatic treatment than to pursue the chimera of a continued attempt to treat the disease as an entity. Apart from uremia, the three conditions desirable to cope with are: Firstly, diminution of urinary secretion; secondly, albuminuria; and thirdly, dropsy. The diminution of urinary secretion is frequently an accompaniment of increased dropsical effusion, hence its difficulty. The two conditions are frequently treated simultaneously, when the diminution in the excretion of water depends upon a subacute attack. Diuretics must be avoided and the case must be treated on the same principles as acute nephritis. On the other hand, when there is no evidence of active engorgement cardiac tonics, such as strophanthus and digitalis, are frequently of great service. Of the two digitalis is perhaps the more useful, but it is frequently necessary to alternate their em-

ployment as in ordinary cases of weakness of the heart. It is sometimes desirable to use theobromine, caffeine, or diuretin, either alone or in conjunction with strophanthus and digitalis. I remember one case in which, although the dose of digitalis had been increased, very little alteration in the quantity of urine passed had been noted until diuretin was used. Of all diuretics, however, water is undoubtedly the best and can be given freely, unless it is found that the dropsy increases while the elimination of urine shows no change. Milk is often employed as a diuretic in these cases, but, as previously indicated, it is undesirable to attempt to limit the patient to any fixed diet.

The work of the kidney is often improved by a temporary rest such as results from the administration of saline purgatives, which are, however, more frequently used with the idea of affecting dropsy than with the simple object of increasing the work of the kidney. Ringer speaks strongly in favor of the use of large doses of iodide of potassium, and he thinks that their diuretic influence is by no means limited to syphilitic cases.

Next, with regard to the loss of albumen, this is sometimes found to be reduced during the early days when the patient must be kept in bed. Of the drugs which have been employed with the object of reducing albumen, the greatest favor has been shown to the class of astringents. Of these the salts of iron are perhaps those which give the best results, though the improvement is often to be seen in a diminution of anemia rather than in a diminution in the loss of albumen. Many of the astringents have the disadvantage of favoring indigestion, and their range of utility is therefore greatly limited. Acetate of lead has been recommended, more particularly in cases associated with much hematuria, but this latter symptom is, I believe, better treated with rest, warmth, and diet than with the administration of drugs. Similar considerations generally affect the administration of ergot, which has sometimes been used with the intention of reducing albuminuria. Tannic acid and gallic acid and the newer combinations such as tannoform and tannalbumin have lately been brought into notice, but, notwithstanding the weakening influence of a great drain of albumen, it is, I believe, desirable to watch the general condition of the patient rather than to concentrate attention upon the albuminuria, since so many of these astringents interfere so greatly with the digestive powers.

The treatment of dropsy may be considered under the headings of treatment with diaphoretics, diuretics, and hydragogue purgatives, though in extreme cases it is necessary to adopt surgical measures of relief. Of the diaphoretics there is perhaps but little room for discussion connected with the external agencies to be employed. Many are in favor of the use of the wet pack, and often before the use of the wet pack the action of the skin may be stimulated by vapor baths or hot-air baths, or even by the use of hot-water baths, and the diaphoretic action may be increased by giving copious draughts of water during the administration of the bath. Turkish baths have been recommended, but these can only be employed in mild cases and are wholly unsuitable when there is much dropsical effusion.

It is perhaps unnecessary to enter into details here regarding the various devices by which patients have been submitted to the action of heated air. More important, perhaps, is the question of pilocarpine. Few drugs have given rise to so much disappointment, although perhaps the reaction at the present time has been rather too great. I have seen some advantage result from its employment as the starting-point of diaphoresis, which has been continued by the subsequent use of the bath. It is well recognized that exceptional cases are from time to time met with in which it is difficult to induce action of the skin, and in these the bath is apt to produce considerable discomfort and headache. In these cases pilocarpine may be tentatively employed, the effect on the circulation and the dyspnea being carefully noted during the administration of the drug. It must not, however, be forgotten that although some observers praise pilocarpine, there is considerable evidence of dangerous results from its employment; thus Proben (*New York Medical Journal*, July 18, 1896) has found that it causes an increased frequency of the heart's action, the pulsation sometimes increasing forty or fifty to the minute, and that there is a simultaneous lowering of the blood-pressure which he attributes not only to vasomotor paralysis, but also to direct depressant influence on the cardiac muscle; and he states that severe collapse, nausea, vomiting and diarrhea may sometimes ensue. Another contraindication to the use of pilocarpine lies in its influence upon the pulmonary circulation, since it favors rapid transudation and edema of the lungs. Proben indicates a further danger in the pos-

sibility of filling the bronchial tubes with saliva, if the reflex activity of the larynx is diminished owing to coma. Summing up the contraindications to the use of pilocarpine, one must mention progressive weakening of the wall of the heart, either from fatty degeneration or from passive dilatation and conditions of engorgement of the lung, or accumulations of fluid within the pleural cavity. In any of these the drug, if used at all, must be employed with great caution and as a starting-point for diaphoresis, and not as the sole active diaphoretic agent.

It is probably unnecessary to spend time over the benefits to be obtained from the use of saline and hydragogue purgatives. These are so well recognized that it will be unnecessary to do more than to mention the value of sodium sulphate, acid potassium tartrate, sodium potassium tartrate, jalap, scammony, and perhaps mercury. Of the diuretics which favor the removal of dropsy, the salts of lithium, potassium and sodium need only be mentioned. Balsam of copabia has been mentioned, but has been found to be somewhat uncertain in its effects, and hematuria has often been attributed to it.

*Cirrhosis of the Kidney.*—With regard to cirrhosis of the kidney, treatment has to be almost entirely symptomatic, though from time to time certain drugs have been advocated for the treatment of the disease—for example, iodide of potassium in large doses for a length of time has been recommended, and some observers speak highly in favor of the use of chloride of gold and sodium. This treatment has, however, found greater favor in America than in this country, and even those who speak well of it indicate that it occasionally leads to dyspeptic symptoms. Of the symptoms requiring relief in connection with cirrhosis, one of the most prominent is persistent headache. Mild purgatives may occasionally give some relief—more commonly, however, it is necessary to employ remedies calculated to reduce arterial tension. Of these, perhaps the best known is nitroglycerin, which, either in the form of the tabellæ of the Pharmacopœia or as the solution of trinitrin, has been largely employed. Nitrite of sodium has also been used, and more recently other preparations have been added by Dr. Bradbury. It may be remembered that nitroglycerin is more continuous in its effects than nitrite of amyl, although it exerts similar effects in dilating peripheral vessels and thus lowering the arterial tension. This effect of nitroglycerin is perhaps

partly to be explained by its more slow absorption from the stomach, as compared with the rapid absorption of nitrite of amyl from the bronchial mucous membrane, and it is also partly to be explained by the gradual splitting up of the molecules of nitroglycerin after it has been passed into the circulation; the drug is hence particularly adapted to the relief of a chronic condition, while nitrite of amyl finds its special applicability in the relief of the symptoms of more urgent development.

Dr. Bradbury endeavored to find preparations which would be yet more permanent in their power of lowering the arterial tension, and he found that erythrol tetranitrate had this power, and it has accordingly been employed not only in cases of heart disease but also in some of those special forms of headache connected with renal cirrhosis. These special forms of headache have also occasionally been treated with antipyrin and antifebrin, especially when the headache is associated with much pain of a neuralgic character.

Another common symptom which demands special treatment is the tendency to sleeplessness, and this is frequently conjoined with either the persistent headache which has been already mentioned, or with pains of a more neuralgic character which come and go in more irregular fashion. The sleeplessness of renal cirrhosis may sometimes be abated by methods calculated to relieve tension of cerebral vessels. Sometimes sleep may be obtained by employing a hot foot-bath just before going to bed and by wrapping the feet in warm blankets, so as to further maintain the freedom of circulation. Should the patient suffer habitually from coldness of the extremities, sleep may further be favored by the use of a hot-water bottle. Frequently, however, it is found necessary sooner or later to have recourse to drugs, and the selection of a hypnotic for a patient with renal cirrhosis demands considerable caution since, although these patients are generally losing very little albumen, they are also excreting very little nitrogenous waste; hence it is important to avoid employing any remedy which might further interfere with the eliminative work of the kidney. Foremost among such remedies stands opium. Concerning the use of this remedy I venture to think that we may obtain some valuable experiences in the course of this discussion, since, while some observers consider that it is a dangerous drug to use and are never weary of warning against the risk of pro-

ducing uremic symptoms by its administration, others, on the contrary, have recommended its employment with the view of diminishing the severity and frequency of uremic attacks. I must confess that for my own part I am averse to the employment of opium or of any of the salts of morphine for the relief of insomnia due to renal cirrhosis, although I must admit that I have not seen any of the dangerous symptoms so often mentioned in connection with its use. Sir George Johnson was, however, very emphatic concerning the risks of opium and of morphine, and I have, on several occasions, heard him inveigh against the almost criminal folly of using this remedy which, in his belief, had frequently favored the onset or the return of fatal uremic convulsions.

On the other hand, it must not be supposed that in foregoing the use of opium and of morphine one is in favor of taking no measures to treat the insomnia. Many years ago, when the employment of hyoscine, which has lately been rendered official in the Pharmacopœia, was still in its infancy, I had to treat a patient with renal cirrhosis for troublesome insomnia, and I endeavored to use the then new hypnotic, and administered subcutaneously a dose of one-hundredth of a grain. The result was somewhat curious. The patient almost at once sank into a quiet, tranquil sleep, and the pulse, which had previously been somewhat irregular, became steady. The following morning he told me that he had had a most delightful night and that he had slept soundly all through; but this account did not coincide with that given by the nurse, who said that shortly after I had left him the patient commenced to exhibit symptoms of delirium, and that he appeared to be under the impression that he was present at a supper party of a somewhat gay character, that he shouted instructions and orders and occasionally sang scraps of comic songs of some antiquity and of doubtful propriety; in other words, the dose employed, although it procured unconsciousness for the patient, caused delirium of a type so commonly seen with belladonna poisoning, and accordingly, on subsequent occasions when this patient complained of sleeplessness, I employed a smaller dose with equally satisfactory results to the patient and with far less fatigue to the nurse.

Of other hypnotics which have given satisfaction in this form of sleeplessness must be mentioned sulphonal and paraldehyde. The former I employ somewhat largely, and al-

though it is but sparingly soluble, and although it acts somewhat tardily, yet its administration has, in my experience, generally been followed by good results. Moreover, I have found that it is possible gradually to reduce the dose of sulphonal after the habit of sleeplessness has once been broken. The question of hypnotics, however, formed the subject of debate at the meeting in Montreal, and it may perhaps be inadvisable to reopen the discussion in this direction, since at Montreal the various speakers said almost all that there was to be said concerning the employment of hypnotics.

It is somewhat difficult to draw a sharp line of distinction between the treatment of many of the symptoms of cirrhosis of the kidney and the treatment of one of the forms of uremia, since under the term uremia must be included a consideration not only of uremic symptoms of an acute and violent character, which constitute uremic convulsions, but also of a more chronic type, in which the symptoms frequently simulate those due to diseases of less severity; thus, as examples of chronic uremia must be mentioned the dyspeptic troubles which frequently seem to occur in the course of renal cirrhosis and may assume a severe type before its close, when vomiting and diarrhea may both become persistent and uncontrollable. As the distinction is therefore so difficult to make, I shall perhaps be pardoned for a gradual transition from the medicinal treatment of chronic nephritis to the treatment of uremia.

The treatment of dyspepsia is perhaps of greater importance in the early stages of renal cirrhosis, since there is very little doubt that prolonged attacks of dyspepsia may favor the onset of this disease. It is, I think, no mere coincidence that I have found a very large proportion of patients with symptoms of cirrhosis occurring amongst those who admit the existence of chronic dyspepsia from an early age, and frequently in connection with bad teeth. It is well known that patients who, either on account of defective teeth or from other conditions of their life, get into the habit of bolting their food suffer from dyspeptic troubles, and amongst these troubles must be reckoned the alteration in the character of the urine. Those who pass uric concretions frequently are also prone to exhibit indications of chronic renal changes, though in these cases possibly the albuminuria takes its origin in irritation of the kidney. Hence it becomes important to rectify any errors of diet, any errors of habit, or

any errors of digestive functions, if these are within the range of medicinal treatment. Sometimes benefit may be obtained from the use of the ordinary digestives, from the administration of pepsin and hydrochloric acid, from the employment of diluted hydrocyanic acid, or from the salicylate of bismuth or other bismuth preparations, but in advanced cases of the disease these remedies are generally powerless, and the symptom then has to be treated as one of uremia rather than as one of simple chronic dyspepsia.

Turning now to the treatment of acute uremia, the condition marked by convulsive seizures which may be repeated at frequent short intervals, the treatment naturally divides itself into two groups: (1) the treatment during the convulsion, and (2) the treatment during the intervals between the convulsions. During the convulsions various vaso-dilators have frequently been employed, and those which appear to have been most hopeful are those which act most promptly. Foremost stands nitrite of amyl, which can be administered by inhalation to an unconscious patient. Other nitrites and nitrous compounds have also been used, such as nitrite of sodium, nitroglycerin, either in the form of tabellæ or of the official solution of trinitrin. In my hands these have not given much encouragement. The duration of the convulsive seizure has not appeared to be reduced by their employment, nor has the frequency of the seizures been diminished, and although these remedies undoubtedly possess great power of lowering the blood-pressure by the dilatation of the smaller arteries, they seem to find their chief applicability in the relief of headache, or neuralgic symptoms which result from persistent high tension, and to be of comparatively little service, if any, in the treatment of uremic convulsions. The severity of an attack may sometimes be controlled by the inhalation of chloroform, but this must be used with considerable caution, since the heart is frequently weakened and the patients are therefore not fit subjects for the prolonged use of anesthetics. More hopeful is the treatment with purgatives or with diaphoretics, but in many cases of uremic convulsions one is tempted to defer the use of diaphoretic measures until the convulsions have ceased. Although the convulsions may succeed each other with great rapidity, the individual convulsion commonly does not last very much longer than the ordinary epileptic seizure, and it is therefore frequently impossible to

employ any remedy at all during the convulsive attack, and treatment accordingly has to be confined more purely to the subsequent coma.

For rapidity of action and for efficacy no remedy can compete with croton oil, which may be administered with great ease even to an unconscious patient, and it is the more desirable to employ a strong derivative of this nature on account of the comparative frequency with which uremic convulsions may be associated with symptoms of a hemiplegic type, in all probability dependent upon rupture of one of the cerebral vessels. Under such conditions, therefore, the value of any remedy which will speedily deplete the vessels and thus diminish the risks of hemorrhage can scarcely be overestimated. With uremic coma pending the action of croton oil, it is frequently advisable to endeavor to stimulate the action of the skin, and this may be effected in some instances by the use of a wet pack, or hot air, or vapor bath, as has been previously mentioned in connection with the treatment of dropsy. Even these measures, however, require to be used with great care, since it is not uncommon for it to be extremely difficult to excite the skin to act, and unless free diaphoresis is produced there is some likelihood of increasing the frequency of the uremic convulsions.

Perhaps the most debatable question connected with the treatment of uremia lies in the use of morphine or of opium. These remedies, more particularly the former, have been credited with the power of diminishing the frequency of uremic attacks, and it has been asserted that periods of special danger may be safely tided over by the employment of morphine injected hypodermically. On the other hand, numerous observers consider that there is great risk in the use of morphine in the treatment of uremic convulsions, and I must confess that I should prefer to treat either convulsions or coma by measures calculated to remove nitrogenous waste from the system rather than by measures which, while they quiet the nervous system, at the same time diminish the eliminative work of the kidney.

It will be noted that I have said nothing in this connection of the use of diuretics, and I have intentionally avoided mentioning them hitherto because the relief afforded is likely to be both slower and more uncertain than that which may result from either hydragogue purgatives or diaphoretic measures. Further, when patients are suffering from

uremic symptoms we have in that fact strong evidence that the kidney is not capable of performing efficient work, and therefore it seems rather an anachronism to employ stimulant remedies intended to promote the work of the kidney.

With uremic convulsions in chronic nephritis there is every probability that very little of the renal structure is capable of doing work, and this difference in the symptoms of acute uremia must be carefully contrasted with the condition of acute uremia occurring in connection with acute nephritis. In the latter, although the work of the kidney may be temporarily arrested owing to renal engorgement, there is fair ground for hoping that if this engorgement can be reduced for a time by relieving the engorged vessels through the eliminative action of the skin and the bowels, the normal circulation will once more be reestablished through the healthy portions of the kidney and the renal secretion will once more be resumed. With chronic nephritis, on the other hand, such hopes are likely to prove fallacious, unless this symptom occurs suddenly as the result of a subacute attack. There is, of course, very little room for discussion connected with the dietetic treatment of uremia after it assumes the acute type, since patients are so frequently reduced to the condition of coma, during which it is difficult to do otherwise than to employ liquid forms of diet. This perhaps forms the chief reason for the use of milk and of beef tea in nephritis, unless complicated by subacute attacks; but when we are dealing with a case of coma or with a case marked by frequent convulsions, we must simply do the best we can, and the best, under such circumstances, must consist in a liquid form of dietary.

In connection with the benefit to be derived from repeated tapping and venesection in chronic kidney disease, especially in uremia, a recent paper and discussion at the Royal Medico-Chirurgical Society becomes of interest. The writer of the paper maintained that in cases of edema it was possible and desirable to keep the legs down and to thus attempt to drain fluid from the trunk and upper limbs, and in the course of the discussion he further explained his belief that it was possible by these means to remove accumulation of fluid from the pleural or peritoneal cavity. He laid great stress upon bringing the fluid down to the feet by a slanting bed. I should much like to hear the experience of others regarding this

change of posture and treatment, since although one has frequently seen much relief follow the removal of fluid from the legs by Southey's tubes or by small incisions, I have not in any case witnessed the draining of the pleural cavity which would be attributed to such an alteration in the posture of the patient. One has often seen patients improve in a marked way after the removal of fluid from the extremities, but by posture alone I believe it is quite impossible to drain fluid from the peritoneum, the pericardium, or the pleura.

In conclusion I venture to think that the subjects which may most usefully be discussed are:

1. The question of expatriation, of occupation, and of the administration of alcohol.
2. The possibility of limitation of albuminuria by the administration of drugs.
3. The treatment of acute uremia by bleeding, by nitrites, by morphine, and by intravenous injections of water, or by transfusion.
4. The treatment of chronic uremia by nitrites or by the separate treatment of the individual symptoms of chronic uremia.

#### THE TREATMENT OF CORYZA.

In the *Revue de Thérapeutique Médico-Chirurgicale* of May 15, 1898, GALOIS is credited with giving the following treatment in coryza. As abortive treatment frequent inhalation of the vapor of tincture of iodine, cologne water or chloroform, or the following prescription:

- ℞ Pure carbolic acid,  
Ammoniac, of each 1 drachm;  
Alcohol (90-per-cent.), 2½ drachms;  
Distilled water, ¼ ounce.

Every half hour place a few drops on a handkerchief and inhale.

Or, on the first day, every two or three hours the following powder may be snuffed up the nose:

- ℞ Hydrochlorate of cocaine, 2 grains;  
Boric acid, 3 drachms;  
Salol, 3 drachms;  
Menthol, 2 grains.

Or,

- ℞ Salol, 1 drachm;  
Boric acid, 6 drachms;  
Tannin, 15 grains;  
Salicylic acid, 15 grains.

To allay irritation of nasal orifices the following salve may be used:

- ℞ Subnitrate of bismuth, 1 drachm;  
Vaselin and lanolin, each 1 drachm.

As a palliative treatment the congestion may be relieved by atomization into the nostrils of the following solution:

- ℞ Hydrochlorate of cocaine, 15 grains;  
Distilled water, 3 ounces.

Or a pinch of the following powder may be snuffed up the nose every three hours:

- ℞ Hydrochlorate of cocaine, 15 grains;  
Subnitrate of bismuth,  
Milk sugar, of each 3 drachms.

Should the patient be very susceptible to cocaine, menthol may replace it, and the following may be injected into the nostril every two hours:

- ℞ Menthol, 2 grains;  
Sterilized olive oil, 2½ drachms.

Or this ointment may be inserted into the nostril:

- ℞ Menthol, 3 grains;  
Vaselin and lanolin, of each 1 drachm.

During the acute stage care should be taken not to use a syringe for washing out the nostril, lest the Eustachian tube be infected. After this acute stage is passed and the muco-purulent secretion is present, the nasal cavities may be washed out with a four-per-cent. solution of boric acid, or a 1:400 solution of salicylate of sodium. In the early stages it may be wise to use hot foot-baths and antipyrin to relieve the neuralgia, headache, and febrile involvement. Should a young infant be attacked by severe cold it is not safe to use cocaine, but a few drops of a solution of menthol of the strength of 15 grains to 1½ ounces of sterilized olive oil should be dropped into the nostrils. A four-per-cent. solution of bicarbonate of sodium may be used to dissolve and loosen secretion after it has set in freely. In case of syphilitic coryza in the new-born, after the nostrils have been well cleansed, the following ointment should be inserted:

- ℞ Calomel, 15 grains;  
Vaselin and lanolin, of each 1 drachm.

Mercurial ointment should also be well rubbed into the thin portions of the skin every day, and the above ointment should be inserted into the nostrils not less frequently than twice a day.

THERAPEUTIC GAZETTE with AGE and MEDICINE .....	4.00

Foreign subscriptions may be ordered either through our European branch, 21 North Audley Street, Grosvenor Square, London, W.; or through our agent in England, Mr. H. K. Lewis, Medical Publisher and Bookseller, 136 Gower Street, London, W. C. Price, 10s. Remittances may be made either by Postal Order or Stamps.

Price to Foreign Subscribers direct (*postage included*), \$2.50 (10 shillings). English postage-stamps received on remittances.

Editorial communications should be addressed 222 South Fifteenth Street, Philadelphia. Articles intended for the Original Department of the GAZETTE will be accepted only with the understanding that they are contributed to it exclusively.

Authors will receive reprints in pamphlet form, without charge, provided the request for them be written on the articles sent.

Business communications should be addressed to

**WILLIAM M. WARREN, Publisher,**

Box 484.

DETROIT, MICH.

### THE ANTITOXIN PATENT.

In the August issue of the THERAPEUTIC GAZETTE we called attention to the fact that Emil Behring had applied for and been granted a patent upon the antitoxin of diphtheria and pointed out some of the reasons why such a patent should not be granted from the point of ethics and justice, and because its award to Behring distinctly perverts the intentions upon which we believe the Patent Office is based. The medical journals of the United States since then have come out in universal opposition to the patent, and medical bodies have expressed their views to the effect that our position was correct. The following resolutions passed by the Academy of Medicine of Nashville, Tenn., indicate the feeling of all right-minded medical men in regard to this important matter:

NASHVILLE, TENN., Sept. 13, 1898.

The United States Patent Office having granted to Emil Behring letters patent for the exclusive manufacture of diphtheria antitoxin, the Nashville Academy of Medicine declare that this grant is not warranted by Professor Behring's connection with the discovery of this product, his share in the discovery thereof not being greater than that of several other investigators.

Diphtheria antitoxin has been manufactured in the United States by various firms and also by State boards of health for some years without hindrance or attempt at restraint. The product manufactured under the name of

Behring has been proven inferior to the serums of American producers, and if the stimulus of competition be removed by the establishment of a monopoly, the tendency will be rather toward a deterioration of this product than toward its improvement.

The Academy therefore protests that the granting of letters patent in this case is detrimental to the best interests of science, the medical profession, and the thousands of sufferers from diphtheria, and that as a matter of common justice the grant of patent rights should be revoked.

The Academy further directs that this protest shall be furnished to the medical journals of this country for publication.

### THE ACTION OF SALINE PURGATIVES.

Since the time of the classical researches of Hay and of Rutherford upon the action of purgatives, there have not been many papers of very great importance upon this subject, although from time to time minor researches concerning it have been published by Hofmeister, Hedin, Höver, and others. It will be remembered that Hay decided, as a result of his studies, that saline purgatives always excite more or less secretion from the alimentary canal and that low diffusibility of the salt impedes the absorption of the secreted fluid. The practical import of his studies was that with the average saline it was wise to give it in concentrated solution, when a free watery evacuation was desired, since its power to purge disappears to a great extent with the dilution of the solution.

A still more recent study of considerable interest has just been published by Wallace and Cushney in the *American Journal of Physiology* upon the subject of intestinal absorption and saline cathartics. These authors first point out that Heidenhain came to the conclusion that two distinct factors were involved in the action of salines, namely, the osmotic influence of the solution and the physiological activity of the bowel. On the other hand, Hamburger, while accepting the theory of osmotic action, has attempted to show that the physiological activity, so-called, is really a combination of certain physiological forces. Recent researches which have been made indicate that red blood cells and their tissues imbibe solutions of certain salts more freely than others, and it is in this line that most of Wallace and Cushney's work has been carried out. They noted at the beginning of their research that most of the saline cathartics depend upon the anion, or acid constituent of the salt, for their purgative properties. Thus, it is a well known fact that sodium sulphate, potassium tartrate, sodium phosphate and similar substances act as purgatives, while sodium chloride, potassium

chloride, etc., do not possess this action to any great degree. When we come to the magnesium salts it is found that not only the anion or acid constituent determines the purgative property, but the cation or basic constituent also possesses a purgative property, and this is indicated by the fact that magnesium chloride and magnesium carbonate possess purgative action, although they do not contain sulphates or tartrates.

The method of experimentation resorted to by these investigators need not be discussed here, as the details of the method are purely technical; suffice it to state that their ability to do original work, coupled with their studies of other investigators, has enabled them to devise means which are distinctly reliable. Experimenting with a large number of substances they found that some were rapidly absorbed in the stomach and small intestine, while others were slowly absorbed and reached the large intestine before absorption took place, the result being that such salts not only acted by an influence which they might exert upon the intestine itself, but supplied the intestinal contents with so large a quantity of liquid that the fecal matter was fluid and therefore more readily passed. To express it in other words, the whole of the solutions of sodium chloride and sodium phthalate was absorbed in the course of its passage through the stomach and small intestine, while three-fourths of the citrate and sulphate solutions reached the large intestine. It is the sulphates which are largely found in the natural purgative waters, and as many of these waters are dilute solutions it would seem probable that their purgative properties depend largely upon their not being absorbed from the alimentary canal. Further, dilute solutions of the saline cathartics are not only slowly absorbed themselves, but they retard the absorption of fluid from the stomach and small intestine and so aid in a secondary manner in the production of fluid stools. Further than this, some natural mineral waters contain in addition to their purgative salts insoluble calcium salts which still further tend to retard absorption in the intestine. It is evident, therefore, that saline purgatives act in three ways: First, by causing an outpouring of fluid from the surrounding tissues into the intestinal canal; second, by increasing the liquid in the intestinal canal by their presence; and third, by preventing the absorption of other fluids which would otherwise be taken up into the general tissues.

#### THE INFLUENCE OF DRUGS UPON BILIARY SECRETION.

Readers of the THERAPEUTIC GAZETTE will remember a research which was published by Pfaff and Balch, of Harvard University, about a year ago in the *Journal of Experimental Medicine* upon the influence of various drugs upon the secretion of bile, the subject of the experiment being a woman with a biliary fistula. These investigators found, it will be remembered, that the drugs which are ordinarily supposed to possess cholagogue properties exercised practically no influence over biliary secretion, the greatest flow of bile being caused by the ingestion by the patient of ox-gall. In the *British Medical Journal* of June 25, 1898, a somewhat similar, but less exhaustive, paper is published by Dr. William Bain as a contribution from the Physiological Laboratory of St. Thomas' Hospital. After pointing out the difficulties in studying the influence of drugs upon bile, both when animals and human beings are used as the subjects of study, he records his case, which was that of a man aged forty-nine who was operated upon for gall bladder disease. He then details the various means which were taken for collecting the bile as it was secreted, the methods which he resorted to in its analysis, and then gives a series of cases which have been previously recorded.

It will be remembered that there exists an extraordinary discrepancy in result upon the part of all those who have so far studied this interesting question. Some of the investigators found that drugs which had no reputation among medical men as cholagogues caused a profuse flow of bile, as for example Battastini and Marfori, who found *santonin* to be the best cholagogue. In Bain's research he studied the effects of a number of mineral waters derived from Harrowgate in England, as the Kissingen Spa at Harrowgate, and from Carlsbad, Bohemia. He also studied the effect of hot water taken before breakfast, *euonymin*, *iridin*, benzoate of sodium, *salicylate* of sodium, and two derivatives of *podophyllum*, namely, *podophyllum-resin* and *podophyllo-toxin*. At the same time that the bile was examined an analysis of the urine was made. Bain found in his patient that the average amount of bile secreted in twenty-four hours in a small man of medium weight approximates 775 cubic centimeters, which is about the same as that estimated by Copeman and Winston, although slightly in excess

of their quantity. It is also considerably in excess of that noted by Pfaff and Balch, who found that the average flow was 514 cubic centimeters. It is, however, proper to remember that Bain's patient took ox-gall daily.

In concluding his paper Bain tells us that more bile is secreted during the day than at night, and that he finds that the old sulphur spring water of Harrowgate, Carlsbad water, euonymin, benzoate and salicylate of sodium and the water of the Kissingen Spa at Harrowgate all increase biliary flow, that podophyllum-resin and iridin increase the proportion of bile solids without increasing the quantity of bile, and that hot water and soda water in pint doses do not seem to increase the biliary secretion. His urinary studies support the view already enunciated by many investigators that the salicylate of sodium increases the excretion of uric acid in the urine. These studies are of interest in that they are confirmatory of a number of views generally held by practising physicians. They explain the beneficial effects of Carlsbad water, of podophyllin and similar substances in cases which are described as being those of hepatic torpor, and they also indicate that the beneficial effects obtained from drinking hot water on an empty stomach depend rather upon the stimulant effect of the heat on the mucous membrane of this viscus and the influence on the portal circulation than upon any direct effect exercised upon the cells of the liver.

---

*THE EFFECT OF REST AND EXERCISE  
UPON THE PERCENTAGE OF HEMO-  
GLOBIN IN ANEMIA.*

---

Under this attractive title a recent contribution has been made to this very important subject, a subject which has received far too little attention from those physicians who recognize the fact that other means than the mere administration of drugs should be resorted to for the cure of disease. Many of our readers probably remember that about two years ago Dr. J. K. Mitchell, of Philadelphia, published some studies on the influence of massage upon the various constituents of the blood. Since then comparatively little work has been done upon this subject, although his paper was to a large extent in a new field. In this connection, therefore, a communication to the *British Medical Journal* of June 25, 1898, by Edgecombe, is of value.

It has been known to physiologists and to clinicians for many years that there are distinct diurnal variations in the blood of

healthy persons both in regard to the hemoglobin and the various corpuscles. Thus Oliver and Edgecombe in 1896 recorded the fact that the hemoglobin might vary as much as a little over seven per cent. in twenty-four hours, that the volume of the corpuscles might vary  $4\frac{1}{2}$  per cent., and that a decrease usually followed the day hours, perhaps because of the dilution of the blood by fluids ingested during the day, but more probably by reason of the wear and tear of increased activity during the period in which the patient is awake. In confirmation of this view Edgecombe has made some interesting studies in which he has proved that when a person works during the night and rests during the day a reverse process takes place, so that instead of his highest percentage of corpuscles and hemoglobin being in the morning, the lowest percentage occurs at this time if the patient has worked all night. He further found that exercise produces a very distinct influence and that active exercise increases the extent of the day fall, but also of the night rise, in blood value. He then goes on to point out the bearing of his experiments, which show that there is a physiological foundation for the well known value of rest in bed in the treatment of anemia; and while he found that moderate active exercise was beneficial to the blood, in that it caused a slight overproduction of hemoglobin in healthy individuals, in unhealthy persons whose powers of blood generation is deficient he is convinced that rest accompanied by nourishing diet and passive exercise used in moderation is an exceedingly important factor in producing a cure, and it would seem to us that the value of the rest is in direct proportion to the severity of the anemia which is present. All these new experiments emphasize Dr. Weir Mitchell's clinical insight in introducing the "Rest Cure."

---

*THE PREVENTION OF CAMP DISEASES.*

---

Plutarch states that Cyrus always carried with him water of a certain spring, which he drank from a golden vessel after having it boiled. This naturally suggests that not only were the huge armies which this monarch commanded subject to diseases incident to the use of impure water, but that the sanitary science of the day had reached a much higher state of development than is commonly accredited to it. Certain it is that could the soldier be induced to adopt a pre-

caution much less onerous than that taken by Cyrus—*i. e.*, the boiling or filtering of any apparently clean water—typhoid would practically disappear from the army.

The typhoid fever from which the army has suffered in all its large camps was taken into the systems of the soldiers with the drinking-water. On this point there can be no doubt, though in individual instances the disease may have been contracted from milk as an indirect water contamination, or among doctors and hospital attendants from neglect to disinfect the hands after handling patients afflicted with the disease.

No bacteriological or chemical examination can prove the purity of water in so far as the typhoid infection is concerned, and it is safe to say that no spring or well within an area of five miles of a camp in which typhoid is endemic should be trusted twenty-four hours after such a camp has been pitched. The means of contamination and the probability of its occurring are so obvious as to require no detailed mention.

As long as the sanitary inspectors of camps hold that the water supplied to the men is pure and safe because, for instance, it comes from an area in which there are no houses, and hence should be pure, typhoid once started in camp will spread.

All water should be regarded as dangerous until it is either boiled or filtered; in this belief the soldier should be trained. Boiling is troublesome, often impossible. Filtering is easily accomplished and is always practicable during periods of encampment. When there are many troops assembled in one camp, and the water is piped to the various regiments, the Government could and should establish such a system of sedimentation and sand filtration as has been shown to be an efficient remedy against typhoid. When this is not practicable, there are small filters which render the water absolutely sterile and which, if issued to each company together with a barrel or other reservoir for storage, would at the expense of one man's attention secure an abundant supply of absolutely wholesome water. These filters could also be carried on the march, and during rest periods could render safe the supply from neighboring springs.

The first step towards crushing out the present epidemic of typhoid and toward preventing a recurrence of the disease with each large encampment is absolutely to distrust the drinking-water and to subject all of it to a sterilizing process.

As an occasional means of typhoid infection, perhaps even a frequent means when there are many walking about with latent forms of the fever, may be mentioned the flies, which in Tampa swarmed over everything. The immediate and habitual covering of all dejecta with earth tended to lessen if not entirely to abolish this danger.

Gastro-enteritis—though perhaps this is a misnomer for the anorexia, cramps and diarrhea which constitute the commonest forms of sickness to which the soldier is subject—is usually directly traceable to drinking, while hot and tired, large quantities of cold liquid, often beer, to eating ill cooked or ill-chosen rations, including under this caption raw fruit, to sudden chilling of the surface.

The regimental canteen has proven a distinctly crippling factor in Southern camps, though its action in Western posts may, as has been claimed, be beneficent. It, together with every saloon and soft drink shop within reach of the army, should be closed to the soldier, and the pay-day drunk, diverting in itself, but a good feeder to the sick call, would then be abolished.

The food which the men receive should be inspected by the officers, particularly the company officers and those of the medical staff. It is probable that as the volunteer army now stands not one company cook out of five had any experience in the culinary art previous to the breaking out of this war, and that not one out of eight could on his present merits preside over the kitchen of a third-class eating house. It might be a serviceable reform to have the officers' tables served from the company messes; it certainly would be a great help to have the cooks regularly and carefully instructed in the rudiments of their art.

Raw fruit, even when fresh and ripe, is like beer so fermentable and so likely to cause diarrhea that its consumption should be avoided.

As to the avoidance of surface chilling, the belly-band, which promised much, has as a rule not proven its claims. Some oversight on the part of the company officers would accomplish much in this direction.

It is of cardinal importance that we should clearly realize that the means by which most of the camp diseases may be avoided are well understood and are so simple and practicable that they may be efficiently carried out, provided a sufficient amount of energy is displayed by the company officers and by the regimental doctors.

## Reports on Therapeutic Progress

### AMYLOLYTIC FERMENTS.

In *The Lancet* of May 7, 1898, WINGRAVE of London tells us that personal necessity for a starch cement having suggested a few experiments with several easily obtainable preparations, the experience so gained may prove helpful to others in their selection of a ferment from a group which clinically receives less attention than the proteolytic does.

Starch ferments may be divided into two chief kinds, according to their sources: (a) animal, prepared from glands—ptyalin (salivary), amylopsin (pancreas); and (b) vegetable or diastatic. The preparation of group a is not only attended with some technical difficulty, but the products are too unstable and unreliable to become generally available. Not so those of the second group. These, for the most part, are easily obtained, stable, reliable in action, and economical in price. The best known examples are malt diastase and taka-diastase. Malt diastase occurs in markedly varying proportions in all extracts of malt (moist and dry), while taka-diastase is prepared by making a cultivation of *Eurotium oryzae* (of the *Aspergillus* group) on hydrolyzed wheat bran. The diastatic influence is extracted with water and separated by evaporation as a scaly powder, which is readily soluble in water and possesses well-marked hydrolytic power. Many samples were tested against normal saliva, and the following three examples were eventually selected as fair representatives of the second group: (1) Kepler's malt extract (moist); (2) Wilcox's desiccated malt extract (dry); (3) taka-diastase (dry). These were tested chemically and clinically.

It must be borne in mind that the condition of all test-tube experiments must differ considerably from normal and morbid digestive changes, and, however carefully carried out, the results must only be judged as approximate. The first series of trials was made in order to ascertain which of the preparations possessed the greatest amount of diastatic power. It would be tedious to detail them all, but the following are illustrative and can be done by any one:

First experiment (test-tube): Twenty grains of malt extract (moist), five grains of malt extract (dry), and one grain of taka-diastase were mixed respectively with 100 minims of a five-per-cent. solution of arrowroot, neutral-

ized and placed in a water-bath at 38° C. At the end of twenty minutes the malt extract gave erythroextrin and a trace of maltose, the taka-diastase chiefly maltose and soluble starch, and the desiccated malt chiefly soluble starch. (Saliva gave soluble starch in excess with trace of maltose.)

Second experiment: A thick paste consisting of three ounces of arrowroot (representing a full meal of carbohydrates), boiled with fifteen ounces of water, cooled to 40° C. and rendered faintly alkaline, was placed in a flask with 300 grains of Kepler's malt extract, 150 grains of desiccated malt, and 15 grains of taka-diastase, respectively. The flasks were placed in a water-bath, kept at a temperature of 38° C., and shaken every three minutes. At the end of five minutes the Kepler's malt extract and desiccated malt showed no change, while the taka-diastase could readily be shaken, the paste being broken up, and about one-third appeared fluid. In ten minutes it was only lumpy in the center, and in thirty minutes the lumps had quite disappeared, while the Kepler's malt extract and desiccated malt were nearly as gelatinous as at first. It was found that the products of the taka diastase action were soluble starch, maltose, and erythroextrin, the original arrowroot being entirely changed, while the Kepler's malt extract and desiccated malt only afforded small quantities of sugar, soluble starch, and dextrin. This test indicates that taka-diastase possesses greater hydrolytic power than either of the malt extracts, which may be due either to a higher ferment potential or to a greater range of action under disadvantageous and artificial conditions, such as accumulation of sugar and intermediate products, etc. It was further observed that increase of the temperature up to 50° C. increased the action of the malt extract.

Having considered the behavior of these ferments under what might be termed favorable conditions, the next point was to watch them under morbid influences similar to those occurring in so-called dyspeptics. During pyrosis, lactic, acetic and butyric acids are present in proportions variable yet minute. A sufficiency of each acid was added to starch solutions to produce the well known acid taste, and the solutions were then watched under the same conditions of temperature as in the other tests. In each case the starch was converted, after three times the duration of the exposure used in the other tests, into soluble starch and slightly

to erythrodextrin, but sugar only appeared in very small quantities after three to four hours. The addition of neutral peptones and proteids did not appear to exert any influence. The presence of 0.2 per cent. of hydrochloric acid after exposure for twenty minutes permanently killed all the ferments, but for a less period activity was restored on neutralization. Quinine dissolved in citric acid did not inhibit unless the strength exceeded 0.5 per cent., a point which is of clinical interest, since the author's experience has shown that small doses of one-half to one grain undoubtedly act beneficially in pyrosis. The ferments were then tested with raw starch as represented by scraped fresh potatoes; upon which, like saliva, they had no hydrolytic influence whatever.

Having seen that butyric, acetic and lactic acid retarded the conversion of starch into sugar, their neutralization was obviously necessarily essential to a satisfactory ferment action in cases of pyrosis. A preliminary preparation of the stomach by means of small doses of carbonate of magnesia and chalk in the form of lozenges, or sodium carbonate dissolved in chloroform-water, proved effectual. For it must be borne in mind that, normally, starch conversion is carried on in the stomach, not in the mouth, and it has every opportunity of being completed in the stomach, since hydrochloric acid may not appear free for from half to one hour. But it is extremely doubtful what proportion of work the stomach and intestines respectively perform in a person living at high tension with an irritable digestive tract. As hydrochloric acid is necessary for exciting and maintaining proteolysis, so alkalies are essential for proper starch conversion, and it is almost useless to attempt the digestion of starch in cases of pyrosis without their aid. It is probable that in a very high percentage of cases described as dyspeptic the starch conversion is mainly at fault, and consequently the case shows no improvement under pepsin treatment.

Clinical observation supported the test-tube evidence. The dry malt extract not only acted as a powerful sialagogue, being a pleasant substitute for jam when eaten with bread and butter, but the after-effect undoubtedly gave evidence of a greater diastatic power than the artificial tests led one to expect. The fluid malt extract seemed to increase the pyrosis to such an extent that it had to be discontinued in several cases, while in others the excessive sweetness was

tolerated and its diastatic action seemed satisfactory. Still the excess of sugar and its bulk more than counterbalanced its diastatic value. Taka-dia-*stase*, on the other hand, being free from sugar, is entirely without these disadvantages and its action is unhampered.

The conclusions may thus be briefly summarized: (1) That of the commercial starch or diastatic ferments taka-dia-*stase* is apparently the most powerful and the most reliable, since it is more rapid in its action—*i.e.*, it will convert a larger amount in a given time than will any other amylolytic ferment. (2) That organic acids, such as butyric, acetic, and lactic, the acids most frequently present in pyrosis, etc., do retard but do not permanently kill the ferments, and when neutralized are harmless; that taka-dia-*stase* seems to be less influenced by them, and also by tea, coffee and alcohol, than are saliva and malt extracts. (3) That hydrochloric and other mineral acids quickly stop and permanently destroy all the starch ferments, if allowed sufficient time and if present in sufficient quantities. (4) That taka-dia-*stase* and malt dia-*stase* have, like ptyalin, no action upon cellulose (uncooked starch).

---

#### THE USE OF NITROUS OXIDE GAS AND OXYGEN DURING SURGICAL OPERATIONS.

BELLAMY GARDNER writes on this topic in the *British Medical Journal* of April 30, 1898. He thinks that so many advantages might be claimed for the introduction of an anesthetic agent which would combine the four attributes of safety, a rapid unconsciousness, muscular relaxation, and freedom from after-effects, that a few further remarks on the results which are at present attainable with nitrous oxide gas when mixed with suitable proportions of oxygen may prove of interest as offering the addition to our list of an inhalation less incapacitating than chloroform and ether, but scarcely inferior in value for many surgical procedures of moderate gravity.

The question at once arises, Under what conditions will such an anesthetic be of special value?

1. A complete examination of the pelvis and abdomen is often needed before a diagnosis can be arrived at in cases which may require ether for an operation shortly afterwards; on these occasions, without any special preparation, gas and oxygen will prove a most convenient help.

2. As ether is very safe, in modern days it is no exception to find patients who have inhaled it several times, but suffer considerably from after-effects; to these the substitution of a tasteless gas during a surgical operation is a great relief.

3. Many operations require some further painful procedure during convalescence, the removal of drainage tubes, the moving of stiffened joints, the reopening of a wound for hemorrhage or redressing; in these it is particularly desirable not to upset the patient's digestion by a second dose of ether if nitrous oxide can be made to rise to the occasion.

The apparatus invented by Dr. Frederic Hewitt for use in dental practise is adaptable to surgical cases after a slight enlargement of the oxygen apertures in the mixing chamber, from ten to twenty per cent. of oxygen being required when the face-piece is kept continuously applied. About fifty gallons of nitrous oxide and seven or eight gallons of oxygen are inhaled on the average during each quarter of an hour's narcosis. Beginning with two or three per cent. of oxygen the patient inspires the gases for five or six breaths, and by means of a dial plate the oxygen is then increased in amount, according to the depth and rate of breathing and the color of the ears and face.

We know exactly the symptoms of asphyxia which nitrous oxide given alone produces—namely, cyanosis, jerky, rapid breathing, twitching of the limbs, and dilated pupils. These objectionable results are avoided by the presence of oxygen, and by means of experience in the use of gas alone the amount of oxygen required in each case is discernible the moment respiration tends to vary at all from that of normal softly snoring sleep. Clinically, if the breathing grows faster and deeper and color a trifle dusky, more oxygen is wanted; if quieter and slower, the oxygen must be reduced.

Let us now inquire what type of anesthesia is produced, and the symptoms observable during the narcosis. The color is normal, the breathing of a softly snoring type, not so stertorous as with ether, not so quiet as under chloroform; the pulse is strong, full, and regular; the abdomen is generally quite flaccid, but the limbs may show a slight tendency to rigidity; though the legs will offer no resistance to being placed in the lithotomy position, they may show slight reflexes from time to time. The blood from an incision during this anesthesia may appear somewhat venous at intervals; this is not, however, due

to congestion, but to the fact that nitrous oxide to some extent replaces oxygen in the hemoglobin and the purple color of the new product becomes evident in the flowing blood, even while the facial color is healthy in appearance.

Alcoholic patients are not good subjects, nor are very powerful athletic men, but most women and well nourished persons generally can be regarded as suitable cases, while those who are weakened by illness often take the gases remarkably well.

In the writer's first article on this subject, in *The Lancet* of June 12, 1897, he gave an account of the uses to which he had applied this anesthetic during the previous two years. In the August number of the *British Gynecological Journal*, 1897, he gave a further account of its suitability for certain cases in that branch of practise, citing, in each paper, several instances of its prolonged inhalation. Since that time he has had notes of a number of successful administrations lasting from fifteen to twenty minutes, and in these he has not observed any symptoms which would indicate that the anesthesia has any more definite limits with regard to time than that of chloroform or ether.

The recovery to consciousness after removal of the face-piece has been very rapid, often complete in two to three minutes, and sickness has been conspicuous by its absence.

Such operations as the removal of a cystic adenoma from the breast, dilatation of the cervix uteri, removal of an inflamed hymen, reopening of a lumbar renal incision, opening and curetting of a large mammary abscess, and several cures for varicocele among the number, will illustrate the usefulness to which these gases may attain.

The writer thinks the safety of nitrous oxide and oxygen is greater than that of the former gas alone—the safest of all known anesthetics, for during the past eight years its adoption in dental practise has been rapidly becoming general, and no fatality has ever been recorded under its influence.

#### THE TREATMENT OF ANGINA PECTORIS.

LYON writes in the *Revue de Thérapeutique Médico-Chirurgicale* on this theme. For the treatment of the attack itself, rest, the inhalation of five or six drops of nitrite of amyl and a hypodermic injection of  $\frac{1}{16}$  of a grain of nitroglycerin are to be resorted to. To overcome the syncope ether, caffeine or

camphorated oil, the latter in ten-per-cent. strength, are to be employed. Friction should also be applied to the limbs, and, should there be evidences of pulmonary involvement, venesection must be practised, while if respiration fails rhythmic tractions of the tongue must be performed. Injections of morphine are contraindicated in such cases. In those cases in which the neuritis is apparently due to involvement of the cardiac plexus, morphine may be admissible. Fifteen- to forty-five-grain doses of antipyrin may be given by the stomach or by rectal injection, or smaller amounts of phenacetine may be used, and to the point of pain chloride of ethyl spray may be applied.

For the treatment between the attacks care should be taken that exercise does not immediately follow a meal and that sudden motions are avoided. Mild exercise should be taken, but cold baths are not advisable. Smoking should be refrained from. Massage and friction of the right chest with alcoholic liquids may be resorted to. In regard to the diet, the patient should refrain from all rich dishes and fermented drinks and tea, coffee, and alcohol, and should live largely upon milk, eggs, green vegetables, and properly cooked fresh meats. Water should be taken at each meal. For two or three weeks out of every month 30 or 40 grains of iodide of potassium should be taken a day, and for the remaining days of the month  $\frac{1}{10}$  of a grain of nitroglycerin may be similarly taken. Sometimes it is wise to increase the dose of the latter drug. It is also suggested that counter-irritation should be applied in the form of a hot iron over the precordial region every eight days.

Where there is feebleness of the heart due to myocarditis a combination of digitalis and nitroglycerin is of value.

For the treatment of false angina or cardialgia the medication should consist in nitrite of amyl, antipyrin, bromide of potassium, and applications of ether or chloride of ethyl vapor to the pericardium.

A useful prescription is one composed of Hoffmann's anodyne, tincture of valerian, tincture of digitalis, and tincture of belladonna, of each one drachm. Ten to twenty drops of this are taken at the beginning of the attack.

For the treatment of the cause hydrotherapy is to be resorted to in the form of hot baths; faradization of the painful region and the local application of cold by chloride of methyl spray is useful. Should the attack

be due to hysteria the same treatment may be instituted. If to dyspepsia, a milk diet, with hydrotherapy, is useful. If due to the excessive use of tobacco, this drug must be prohibited and nitroglycerin given as in the case of coronary angina. In the angina due to gout, diabetes, and malaria, relief must be given by remedying as far as possible the arteriosclerosis, chiefly by the use of the iodides.

---

*A CASE OF CRETINISM AFTER FIFTEEN MONTHS' USE OF THYROID EXTRACT.*

In the *Medical Review* of May 7, 1898, TUTTLE records the case of a girl suffering from cretinism who began taking thyroids November 30, 1896, at the rate of one grain a day. This produced vomiting, and the dose was reduced to half a grain per day for ten days, on which dosage her stomach did not rebel. Then on increasing to one grain per day all went well. From this time to December 1, 1897, the writer continued the same dose for reasons given later. Beginning then and until February 1, 1898, she took one grain three times a day, and since then she has taken two grains three times a day. Parke, Davis & Co.'s preparation of dried thyroids has been used throughout with much satisfaction. Before beginning treatment the patient had some bowing of the legs and bending of the spine. Just at this time the writer found an interesting report, with photographs, of two adolescent cretins, approximately the age of this one, twenty-four and twenty-two years old, in whom these early deformities had markedly increased while under thyroid treatment, and during the first efforts of walking. In one of these cases the deformity became so great as almost to cripple her. These reports were by John Thomson, of Edinburgh, and he suggested the resemblance of the symptoms to those of rickets, and advised three prophylactic points: smaller doses of thyroids, an excessive nourishing diet, and avoidance of walking as far as practicable. The writer has tried to follow this advice as much as possible, and yet with it the scoliosis has increased, and also the bending of the legs. During the last four months she seemed at a standstill as regards her improvement, so, notwithstanding the softened bones, the writer increased the dose. She has a very large appetite and does not walk much, but stands by the aid of some stationary object most of the time.

The changes we look for are conveniently grouped under two heads: (1) physical, and (2) mental.

1. The height has increased three and a half inches, but this all took place during the first nine months, as she has grown none since September, 1897. With this growth, the femora and tibiae being bent, and the scoliosis more marked, a larger actual increase in length has probably taken place. Typical changes have taken place in the small bones of the hands and feet, the whole hand and foot, and especially the fingers and toes, becoming much larger and more slender, before treatment being fat and stubby. Indeed, one of the first symptoms noticed by the mother was the necessity of getting her larger-sized shoes, the feet outgrowing a pair before they were worn out. The anterior fontanel, which was wide open at the beginning, is now tightly closed, having become so after about eleven months. In the meantime the head has increased in all its measurements one-half inch, around forehead, from meatus to meatus, and from occiput to root of nose. The circumference of the neck has decreased three-fourths inch, the chest is virtually the same, while the abdominal girth is less by one inch. The teeth are still bad, seeming to be made up partly of the milk and partly the permanent set. No new ones have been cut and no old ones lost during treatment.

The general appearance of the child has changed considerably, and this took place mostly in the first half of the treatment. Her tongue has diminished to normal size and can be kept in her mouth; the lips and bridge of nose are thin, and the eyes wider open. The supraclavicular pads have about disappeared.

She lost weight rapidly during the first six months, and really got to a degree emaciated, but since then she has regained her normal flesh, now weighing forty-one pounds, a gain since beginning of seven pounds, and appears much healthier.

The skin is loose and elastic and has not the thickened feeling it had. The hair of the head has grown freely and seems more normal than it did. In August, 1897, the mammary glands began to develop, and within a month a few coarse pubic hairs appeared.

The most marked change in any of the functions is in the bowels. Before treatment she was obstinately constipated, requiring castor oil twice a week, but since early in the use of the thyroids the bowels have acted naturally almost daily. Another change for

the better is in her ability to stand the hot weather of summer. Each summer, until the last, she has been seriously sick during the excessive heat, so that her mother always dreaded losing her; but last summer she kept perfectly well throughout, bearing the heat as well as the normal members of her family.

After four months of the use of thyroids she first began to walk, an act which she had not learned in seventeen years. She has not improved much in this function since, although she walks some, like a child first learning; but this is partly due to discouraging the mother from urging her.

The mental improvement is not so encouraging. There is a distinct change, but not a great gain. She has changed from a quiet, listless child, to a noisy, mischievous girl, making her care decidedly more difficult. She knows persons and things better than previously, and understands spoken language more, but her powers of expression are still very meager, and her vocabulary small. This can be partially explained by the lack of teaching and training efforts in her surroundings.

Taken all in all, Tuttle thinks her improvement seems to be fairly up to that of other adolescent cretins reported, and will try what another year's feeding on thyroids will produce in the way of interesting changes in her physical and mental state.

---

#### CERTAIN POINTS OF INTEREST IN PHTHISIS.

H. P. LOOMIS sums up many interesting points concerning phthisis in the *Medical Record* of May 21, 1898. It is not of the well known methods of treating phthisis that the writer speaks at first, but of the present status of a new line which will hold a prominent place in the next two years—namely, the serum treatment.

Every one is familiar with the fact that, long before the discovery of diphtheria antitoxin, investigators in various countries had been experimenting with the products of the growth of the tubercle bacillus, Koch's tuberculin being one outcome of this line of work. It was in the media changed by the growth, and loaded with the product thrown off by the bacillus in its metabolism, that the antitoxin for the arrest of phthisis was sought.

The discovery of a serum which had antitoxic properties in diphtheria stimulated a new line of research in reference to phthisis, and many well known investigators through-

out the world are at this moment endeavoring to obtain a serum which, when injected into man, will antagonize the growth, protect against the action of the bacilli, and finally destroy them in the body. The majority of scientists are now working, not with the media on which bacilli grow, but with the body of the bacillus itself—the protoplasm which is contained within the cell.

It is believed that this cell body of the bacillus either contains or elaborates by its cell activity three substances: a fever-producing principle, a general toxin which circulates in the blood of the phthisical patient, and a poison which acts locally and causes the well known lesion of the tuberculous inflammation—coagulation necrosis. Up to the present time the first and last properties only have been isolated; the second is still an unknown quantity, and this fact no doubt accounts for the only partial immunity which can be conferred on an animal by any of the antitoxins as now made. The investigators all seem to be working on nearly parallel lines, seeking for a substance prepared with a view to attacking the bacillus, not in itself, in germicidal fashion, but by destroying the pabulum upon which it thrives, literally starving out the enemy.

At present there are two kinds of products which have satisfied the laboratory workers as exercising a more or less complete controlling influence over the development of tuberculosis artificially induced in animals, viz., remedies which are the product of the germ itself, and serum from animals rendered immune by culture products of the bacillus. To the first belongs Koch's new tuberculin. In the *Deutsche Medicinische Wochenschrift* of April 1, 1897, Dr. Koch described a new tuberculin—T. R. he called it. He claimed far more for this than he ever did for his original tuberculin, and stated positively that with it he could render animals immune and could frequently cure them after they had contracted the disease. Dried tubercle bacilli were taken, finely powdered, and centrifugalized with distilled water. The opalescent solution when tested upon animals gave the tuberculin reaction. The residual germs were submitted to this treatment a number of times, until finally all were practically dissolved or broken up, the cell wall being destroyed. The latter solution in small quantities seemed to exert both an immunizing and curative action in experimental tuberculosis. This preparation is now being clinically tested all over the world. The writer has

not had personal experience with its use. An agent of the importers brought him some bottles last June, but they had become contaminated owing to improper putting up, so he was afraid to make any clinical use of them. Clinical facts, as far as he has been able to learn from published articles, have not borne out Koch's claim for his new tuberculin.

A new antitoxin was introduced last autumn by Hirschfelder, of California. His scientific reputation was such that the product, oxytuberculin, has been extensively tried. It is made by adding peroxide of hydrogen to tuberculin, subjecting them to a steam bath for forty-eight hours, and then adding caustic soda. He then filters and neutralizes the filtrate with boric acid. The discoverer claims that as the result of this treatment the toxin of the tuberculin is converted into an antitoxin.

As far as the writer's personal experimentation with this antitoxin is concerned, on animals it does nothing. Hirschfelder claims that it delays the development of tuberculosis in guinea-pigs. This Loomis has not found to be the case. He has had an opportunity to judge of its action on the human subject in only one selected case. He saw no benefit from its use, but of course this is not a fair test. He has found that it is apt to cause some local irritation. At the present time there are three antituberculous serums being extensively used, but he understands that Babes and Behring are both actively engaged in working out new products.

If the antitoxic serum treatment of tuberculosis could be freed, for the present at least, from its commercial aspect, and systematic experiments be continuously conducted in hospitals and sanitariums, then this method might be looked to for good results.

The serum most extensively used at present is Maragliano's serum, or as it is commonly called, the "Italian serum," obtained by treating horses with tuberculin and then with virulent culture of the tubercle bacilli. Maragliano says that tuberculous temperature is reduced in all cases with this serum, and modestly claims apparent improvement in the disease in very many cases. The author has had no experience with this serum, but Dr. Walter James gave it with great care and for a long period of time to a patient whom Loomis saw with him in consultation. He states that he "saw absolutely no benefit and no harm from its use;" the patient steadily

lost ground from the beginning, and finally died.

A second serum is Paquin's, known as tuberculosis antitoxin. This is prepared by Paul Paquin, and is used extensively throughout the West. Its preparation and introduction are entirely along commercial lines. It certainly is not an inert substance, as the writer has seen a patient go into a serious collapse within a few minutes after an injection.

A third serum is the antistreptococcus serum. This serum is not an antituberculous serum, but is often given in cases of phthisis with mixed infection. It is claimed for it that by destroying the streptococcus which is so often present many of the annoying symptoms of phthisis are removed, such as purulent expectoration, night sweats, anorexia, and high temperature, and thus it indirectly affects the tuberculous process favorably. The writer tested it last spring carefully, in the New York Hospital, and had daily examination made of the sputum of the patients who were being injected. In none did the microscope show any change in the mixed infection, nor did the patients show uniform improvement.

For a long time the United States Government has been experimenting in the biochemical laboratory of the Department of Agriculture with an antitoxin serum, looking primarily toward finding an immunizing agent, especially for use among domestic animals. A large experimental farm just out of Washington is connected with the laboratory and the work is very complete. Dr. de Schweinitz, the director of the laboratory, last summer wished to have this serum tested clinically at the Loomis Sanatorium, and the writer agreed to give it a thorough trial. The serum being provided by the Government, from purely scientific motives, he was the more ready to test its efficiency. In the manufacture of this antitubercle serum, attenuated cultures, culture fluid, and tubercle bacilli were injected into horses continuously for fifteen months (4459 cubic centimeters of the fluid being injected in some horses). Animals were experimented upon with the serum from these horses. The following conclusion is taken from the Government report: "The experimental results obtained lead undoubtedly to the conclusion that, while the treatment with antitoxin serum is still in the experimental stage and should as yet be used only under the best conditions, we are on the road to success in the treatment of

this disease and nearer our goal than ever before." Some of this serum has been sent to Liberty continuously for the last seven months, and thirty-eight patients have been injected every day or every other day for varying lengths of time with ten minims of the serum. A report of the first fifteen cases treated is here given: The average number of injections given each patient was thirty-eight. No other treatment was employed. All had the benefit of climate and good food. Four were discharged cured, six improved, and five became worse under the treatment. Eleven gained in weight, two remained stationary, and two lost weight.

The writer has always considered that any particular line of treatment carried on with patients who are also under the best climatic conditions may not be a very fair test of its efficacy. So far he has been using this serum lately on a number of patients in his wards in Bellevue Hospital, but the treatment has not been continued long enough to reach any conclusions. If it improves that class of cases, he for one will believe in its possibilities.

Were the writer to formulate such conclusions as he has been able to gain of serum therapy in the treatment of tuberculosis as it stands to-day, they would be as follows: None of the serums have marked or immediate effect on the disease. The question is, Should they be expected to? If one tries all the serums, in a disinterested way, it must be recognized at once that they are certainly not inert substances.

One cannot but be impressed with the moral effect which hypodermic injections have on some patients. The writer has seen, in neurotic patients, fever leave and weight increase under daily hypodermics of water.

Dr. Stubbett, the physician in charge of the Liberty Sanatorium, reports that comparative tables of the results of the treatment of phthisis show a balance in favor of serum, in increase in weight, decrease of expectoration, general improvement, and physical signs.

*AN EXPERIMENTAL STUDY OF FAT  
STARVATION, WITH ESPECIAL REF-  
ERENCE TO THE PRODUCTION  
OF SEROUS ATROPHY  
OF FAT.*

C. A. HERTER, writing in the *Journal of Experimental Medicine* for May, 1898, says that the experimental study which forms the basis of his paper was originally under-

taken to determine whether the lesions of rickets or similar lesions can be produced in growing animals by withholding fats from their foods as far as practicable. This inquiry was suggested by the alleged frequently low fat content of the milk of women whose children have grown rachitic on breast-milk, by the occurrence of rickets in children fed largely on condensed milk, which is poor in fat, and by the fact that the clinical indications of rickets are often lessened by a diet rich in fats.

The common pig, *Sus scrofa*, was the animal chosen for the experiment, partly because of his omnivorous habits and partly because the nutritive vigor of this animal seemed likely to render possible the extension of the necessarily depressing experiment over a long period of time.

The lesions resulting from fat starvation, at least in the case of pigs, do not resemble or even suggest those of rickets.

Prolonged fat starvation leads to the entire disappearance of fat from the adipose tissues. The form of fat atrophy observed as the result of experimental fat starvation corresponds to the serous fat atrophy described by Flemming, and is essentially the same type of fat atrophy as that found in the epicardial and perirenal fat in the human subject as the result of wasting disease.

The lecithins of the brain and the fat of the liver are not materially reduced by fat starvation.

Fat starvation does not lead to advanced serous fat atrophy of the subcutaneous fat if the animal be given a large excess of carbohydrate food or a considerable excess of the carbohydrate and proteid constituents of milk.

Fat starvation causes a very imperfect absorption of the salts of  $P_2O_5$  from the intestine.

#### DRY LABOR: ITS DANGERS AND TREATMENT.

G. L. BRODHEAD in a paper with this title in the *Medical Record* of May 14, 1898, first discusses the general facts about dry labor, and then passes from the dangers and their symptoms to the treatment. Many cases do badly for the reason that they are treated as cases of normal labor. The writer maintains that the early rupture of the membranes puts a new phase, so to speak, on the labor, and certain plans of treatment, which in normal cases are unnecessary and unadvisable, seem to produce good results in cases of dry labor.

Let us take for consideration, first, those cases in which the membranes rupture before labor sets in. In every case, whether before labor or during labor, even though an examination has been made a short time before, a careful examination should be made as soon as possible after the rupture of the membranes or their reported rupture. Some women are mistaken in their diagnosis of the condition, but it is far better to assure one's self of the exact condition of affairs. By doing so we verify or disprove the woman's statement, detect any accident, such as that of a prolapsed cord or small part, and, moreover, are able to make the diagnosis of presentation and position an accurate one. Again, it is perhaps needless to state that, if the case be one of malpresentation, operative interference immediately after the rupture of the membranes will be possible, and with excellent chances of success; whereas the failure to learn the exact condition at once may result in the death of the child, the correction of the abnormal presentation being later impossible.

After one careful examination has been made, however, further efforts should be infrequent, and then not be prolonged, for in some cases, as stated, the presenting part in its descent blocks up the point of exit of fluid, and further escape is thus prevented. This is, of course, most favorable to the child, and we may in further examinations undo, as it were, the assistance which Nature has kindly given us. After the rupture of the bag of membranes, the sooner labor commences the better, as a rule, will be the prognosis. The writer's plan in these cases is to administer at once a large dose of castor oil and glycerin, followed shortly after by ten grains of quinine sulphate, to be repeated every three hours, with one-thirtieth grain of strychnine sulphate every two hours, careful watch being kept for unpleasant effects of either. These drugs, he believes, aid in the induction of labor, and given during labor seem to increase the number and strength of the contractions, in some cases at least. Under close observation they can do no harm, and serve to stimulate the patient to a certain extent as well. At this time women are able, it has seemed to the writer, to take much larger quantities of these two drugs than at any other time, without unpleasant effects.

Before the digital examination is made the genitals should be scrubbed with soap and water (the official *sapo viridis* being prefer-

able); then with a solution of bichloride 1 to 2000, or a solution of lysol one per cent. After the examination a sterile pad of gauze, covered over with a towel or small vulvar pad, should then be placed over the vulvar outlet, and changed as often as saturation with amniotic fluid makes necessary. In this way the vagina can be kept free to a certain extent from the entrance of "outside" infection. Another procedure, which has been followed by excellent results, is the use of vaginal douches of lysol in one-per-cent. solution, as hot as can be borne, one being given every six hours, to the amount of about three quarts. These douches will keep the vagina sweet and clean, will leave the mucous membrane smooth and soft (acting in just the opposite way from bichloride solution), will stimulate uterine contraction, and in some cases seem to soften the cervix somewhat. Here again the importance of absolute cleanliness must be emphasized, for unless these douches can be given with the greatest care they may easily be the cause of the introduction of septic material. When, now, the membranes rupture during the first part of labor, the treatment as outlined above is carried out, with the exception of the cathartic perhaps. This can be given or not, according to the necessity.

The use of chloral and opium in dry labor must be a guarded one, the danger of asphyxia and protraction being always kept in mind, and it being remembered that these cases often need stimulation rather than a period of rest, during which time more and more fluid is escaping. The fetal heart should be carefully noted before such drugs are administered. The writer recalls one case in which chloral was administered in the latter part of the first stage, the fetal heart being then somewhat more rapid than it had been during the earlier part of labor. Very soon thereafter the fetal heart became so much more rapid that the forceps was used, the cervix offering practically no resistance. Meconium was found when the blades were introduced, and in spite of a quick delivery, made more difficult by the sluggish action of the uterus induced by chloral, the child was born deeply asphyxiated and was with only the greatest difficulty resuscitated.

Several months ago, at the Sloane Hospital, in the attempt to induce labor on a patient with deformed pelvis, the membranes were accidentally ruptured and a considerable amount of amniotic fluid escaped. When informed of the condition of affairs, Dr. Tucker,

who was then in charge of the hospital, advised that the vagina be tightly tamponed with sterile gauze, in order to hold back as far as possible the escaping fluid, both for the sake of the child and to aid in softening and dilating the cervix. This procedure, of such great value in abortion and placenta prævia with rigid cervix, proved in this case to be of apparently great assistance, the cervix dilating perfectly within a very few hours. Having seen the good effect of the tampon in one case, the question has arisen in the writer's mind, Would it not be a good plan to apply such a tampon as a routine procedure in all cases of dry labor? At present the writer is unable to state any results from following such a plan, but theoretically at least it should be successful. When the progress of labor is very slow, he believes it is best to stretch the cervix a little every few hours, a preliminary vaginal douche of lysol having been given. Care must be taken also that the strength of the patient be kept up in every possible way, by the use of plenty of nourishment and stimulants if necessary.

Now, is operative interference ever advisable during the first stage of a dry labor, except when complicating conditions—such as eclampsia, hemorrhage from placenta prævia, etc.—arise, or when from any cause the condition of mother or child strictly indicates operation? In the writer's opinion there is one condition of affairs in which much good can be accomplished, namely, in breech presentation. When a breech labor is protracted in the first stage, even though as yet no symptoms of danger are present, we are justified in giving the patient a little chloroform, the vagina having been first thoroughly cleansed, and in introducing the hand for the purpose of bringing down one foot, preferably the anterior, with which to make traction from time to time. If this be done early, it can usually be accomplished with no great difficulty, whereas later on it may be a very difficult matter. If both legs are extended, the operation will accomplish even a better result, in that it will have broken up the existing "wedge," at a time when the operation is comparatively easy. After the escape of a large amount of liquor amnii, it is sometimes a difficult task to grasp a foot lying high up in the uterus, and the difficulties increase the longer the operation is delayed. If danger symptoms are present, or if for any intercurrent condition it becomes necessary to deliver at once, the usual methods of cervical dilatation, forceps or version, are to be used.

When we come to the consideration of the second stage of dry labor, the statement just made with reference to the first stage holds true here as well. But in the absence of danger symptoms the question arises, How long shall we wait, in the second stage, for its natural termination? It is very difficult, and in fact impossible, to fix any definite period of time; but in the writer's opinion, if in one-half hour after the commencement of the second stage there has been little or no advance, the forceps (or extraction if the breech presents) is advisable, chiefly in the interest of the child, but with the welfare of the mother also in view. He has never had occasion to regret early operation in the second stage of dry labor, but there have been many, many children lost owing to delay at that time and the failure to interfere promptly.

Reference has already been made to lysol for vaginal douching, and its use preliminary to all operative measures is a most excellent one. It not only cleanses the parts very thoroughly, but leaves the mucous membrane smooth and soft, thus making any operative procedure much easier and the liability to laceration far less. Early interference in these cases is obviously in the interest of the soft parts of the mother, for time can be allowed to preserve their integrity, whereas if operation be undertaken when meconium is being passed or the fetal heart is already bad, the welfare of the child demands speedy delivery, with consequent laceration oftentimes of vaginal and perineal tissues.

In closing, the author emphasizes the great importance of dry labor, the possible dangers, chief among which is fetal asphyxia, and the belief that with close observation and prompt energetic treatment our statistics both for mother and child will be greatly improved.

#### *OPIUM IN HEART DISEASE.*

In the *Canadian Practitioner* for May, 1898, MCPHEDRAN, of Toronto, writes on this neglected but important subject. He begins by asserting that with few exceptions the symptoms of heart disease arise from deficient power in the heart to meet the demands made upon it. This is true whether the excess of work thrown upon the heart be due to disturbance of the circulation by disease of the valves, or to degeneration of the wall of the heart, reducing its power below the requirements of the circulation. Our conceptions of heart disease are so intimately

associated with disease of the valves that too often the two conditions are looked upon as identical, or, rather, that the changes in the heart wall are secondary to the disease of the valves.

The valves are but mechanical structures, and disease of them, apart from infective processes, gives rise to symptoms only as it deranges their mechanical action, and thus leads to disturbance of the functions of the heart, and through this to degeneration of the cardiac walls. Cases resulting from lesions of the valves form only a small proportion of all the cases of heart failure.

Pathological changes in the heart occur much more frequently as part of disease of the general vascular system. It is in such cases that the most mature judgment is required in estimating the amount of injury to the cardiac muscle and its powers of recuperating, as well as the best means to be adopted to restore its powers so that they may be adequate to the demands made upon them.

In the treatment of cardiac failure our aim should be twofold, viz., first to reduce the work of the heart as much as possible, and secondly, to stimulate and strengthen its walls so as to enable them to perform their work adequately.

Of the means at our disposal to reduce the demand made on the heart, the most important is, of course, rest. By rest we seek to relieve the heart of all work except that necessary purely for the maintenance of life. Many patients are restored again and again from incompetency of the heart by rest in bed alone. Each recurring attack of failure is more easily induced than its predecessor, and the restoration of competence is effected with more difficulty, until rest alone is unequal to the task of restoring effective power to the heart.

As the effect of physical labor is to greatly increase the strain on the heart, it follows that the benefit of rest in restoring the failing heart will be much greater in the man engaged in physical labor than the man leading an easy life. In the laborer the heart obtains relief to a much greater degree by rest than does the heart of his more fortunate neighbor. In the former, rest may mean the removal of three-fourths or more of the heart's ordinary labor, while in the latter not more than one-fourth or even less of its work is relieved. Another fact of great importance in the difference between the two is that in the laboring man the diseased heart fails.

early, while in the man of easy life it is not until the heart is far advanced in degeneration that he shows the signs of failure. The former will therefore possess much greater recuperative power than the latter.

When the cardiac changes have advanced so far that rest alone is insufficient to restore competency to the heart's action, the end for a time may be attained by the use of cardiac tonics and stimulants to aid the rest in restoring the equilibrium.

In addition to rest the labor of the heart is also greatly relieved by full elimination of the waste products in the blood through the kidneys and bowels. It is probable that this in a great measure affords the explanation of the great benefit often reported from the use of calomel in cardiac disease with dropsy. Any purgative that causes free liquid evacuations will do good.

If the circulation is in fair condition, the drinking of water on an empty stomach is probably the best diuretic, and therefore the most efficient stimulant to elimination by the kidneys. Any remedy that increases the force of the circulation will, of course, proportionately increase the excretion by the kidneys.

In advanced cardiac disease, especially after repeated failures, complete rest of body and mind, aided by free administration of cardiac stimulants and tonics and the judicious use of purgatives, often fails to give relief. The signs of cardiac incompetency increase; there is increasing dropsy and dyspnea with insomnia. The rest of the body is not sufficient to bring the needed rest to the heart; it remains irritable; its action becomes increasingly irregular. The patient grows weaker, the paroxysmal dyspnea increases. Almost as soon as he falls asleep a severe attack of dyspnea causes him to awake and sit up in bed. The distress from the dyspnea is great, but that from want of sleep is greater. These are cases in reality of *angina sine dolore*. Such a condition is rarely benefited by the freest possible use of digitalis or other cardiac tonics and general stimulants. If the dyspnea is not due in part to effusion into the pleura and edema of the lungs, a dyspnea that is persistent and not paroxysmal as cardiac dyspnea is, there is no remedy so effective in such a condition as morphine. The comfort afforded by a hypodermic injection is almost incredible. Given by the stomach it often fails even in much larger doses, because absorption is so slow, on account of the venous stasis in the mucous membranes of the stomach as well

as of other parts, caused by the impeded circulation. In most of the writings on the treatment of cardiac failure too little is made of the great benefit to be obtained by the use of morphine in such conditions. Many of them make no reference to morphine at all in connection with heart disease; a few place its efficiency in severe heart disease next to digitalis. The writer is inclined to look upon it as even more important than digitalis in these cases—in fact, as indispensable.

---

#### THE AIX-LA-CHAPELLE TREATMENT OF SYPHILIS OF THE NOSE AND THROAT.

This method of treatment is well described in an article by LIEVEN in the *Laryngoscope* for May, 1898. He tells us that the patient arises in the summer at seven o'clock, in the winter at eight o'clock; drinks several glasses of special spring water during a one-half hour promenade; one-half hour later he takes a sulphur bath (95° F.) of twenty minutes' duration. In weak patients breakfast should precede the bath by about one and one-half hours. After the bath the patient rests for one-half hour; he is then ready for breakfast.

In vigorous patients the writer adds the vapor bath to the above plan; this is an exceedingly active stimulant to tissue change. After breakfast the patient receives an inunction at the hands of an experienced rubber. Daily one of the following areas is subjected to the inunction: (1) both thighs; (2) both axillas; (3) breast and sides; (4) back; (5) both arms.

The patient is directed to wear woollen undergarments, which are to be changed only once weekly. The anointed areas are rubbed for twenty minutes, until the parts are almost dry. The patient should be instructed not to wash these areas when bathing. The skin is dried about these parts simply by pressure of the towel to absorb the moisture and thus avoid removing any of the salve. Only those parts which are to be anointed the following day are to be thoroughly washed.

The patient is instructed to rest one-half hour after lunch; then two or three hours' exercise should be taken (promenades in the woods, bicycling, riding, tennis, etc.). About half-past five a draught of spring water (about 300 grammes) is taken. Dinner at seven o'clock. At half-past ten the patient retires. The sleeping apartment at all times should be thoroughly ventilated.

To avoid stomatitis, the patient is directed to cleanse his teeth with the following tooth-powder, after each meal:

- ℞ Salol, 4.0 grammes;  
Resorcin, 2.0 grammes;  
Pulv. irid. flor., 40.0 grammes;  
Calc. carbon, 8.0 grammes;  
Carmin, 0.3 gramme;  
Ol. menth. pip., 10 gtt.

He also directs that the mouth be rinsed every half-hour with the following mouth-wash suggested by Dr. St. Clair Thomson:

- ℞ Liquor alumin. acetic, 100 parts;  
Aq. flor. aurant., 300 parts;  
Aq. dest., 800 parts.

The patient carries this with him constantly in a flat bottle. If after these precautions are observed there are still indications of stomatitis, the gums should be painted every two hours with tincture of myrrh. In spite of these precautions stomatitis may develop, and as a rule makes its appearance about the upper incisors and posterior area of the wisdom teeth, characterized by a detachment of the gums, with the formation of a white zone of demarcation. When this occurs it is not an indication, as is usually supposed, for the cessation of treatment. When such a condition presents itself, the following procedure is adopted: With a small applicator, tufted lightly with cotton, the white deposit between the gums and teeth may be wiped away carefully, and the cleansed area penciled with a seventy-per-cent. solution of chromic acid. The chromic acid solution should not be allowed to diffuse in the mouth, and the patient should avoid swallowing for about twenty minutes. The day following such procedure the patient can usually masticate even hard food.

Moderate diarrhea may be regulated by the following:

- ℞ Decoct. colombo, 4 drachms;  
Tinct. opii, 15 minims.
- M. A tablespoonful every two hours.

A diet of oatmeal gruel, eggs and toast is prescribed for twenty-four hours; also the drinking of tea without sugar, and claret.

Cases of severe mercurial poisoning are of very rare occurrence. Patients who have exhibited poisoning symptoms at home or in sanitariums, after the administration of small quantities of mercury have demonstrated their ability to undertake a six or eight weeks' course of treatment in Aix-la-Chapelle without the slightest sign of mercurialism. The author attributes this fact to the stimulation of the tissue metamorphosis

by the thermal baths, and the internal use of the sulphur water. Secondly, the apparent cause of this successful course of treatment in Aix-la-Chapelle, where large quantities of mercury may be exhibited without bad effect, may be due to the favorable influence of the baths, which seem to diminish the toxic effects of mercury. The researches of Grabower have established the fact that the influence of sulphur on mercury causes the conversion of large quantities of metallic mercury into HgS, and that this combination, by reacting in a milder and more constant manner, produces a powerful anti-syphilitic effect, as already mentioned. The writer combines with the course of treatment here described, for tertiary syphilis of the nose and throat, the internal administration of from two to six grammes of potassium iodide daily. In anemic patients he prescribes the iodide as follows:

- ℞ Potassii iodidi, 30 grammes;  
Ferri citrat. ammoniat., 4 grammes;  
Tinct. nuc. vomic., 8 grammes;  
Aquæ destillat., 30 grammes;  
Tinct. cinchonæ comp., q. s. ad 120 grammes.
- M. S.: Two to four teaspoonfuls daily in water.

After the disappearance of the gummata and the healing of ulcerations, the iodide administration is discontinued. In the writer's opinion, the iodides exert their influence only as resorption agents of the products of tertiary syphilis; the poison itself and the hypothetical bacteria can be influenced only by mercury.

As regards diet, in the course of treatment prescribed at Aix-la-Chapelle, especial stress is laid on the administration of nourishing food, to build up the strength of the patient. No restrictions in diet are given, with the exceptions of sweets, strong salads, and cheese. By this exclusion there is less predisposition to diarrhea.

As to drinks, two or three glasses of Münchener beer or a half bottle of French claret are allowed in the evening. Alcoholic drinks are absolutely excluded.

In addition to the general therapy, careful attention to local treatment of the nose should be given; this is especially directed to the removal of the foul-smelling secretions, and also to the careful disinfection which follows the breaking down of the tissue in the nasal cavities.

The crusts are removed by sprays of thermal water or lifted out by the forceps. The coarse residue may be removed by the daily use of the Gottstein cotton tampon; this may

be covered with a ten-per-cent. euphen salve. The ulcerations are penciled with a seventy-five-per-cent. solution of chromic acid; this should be done under good illumination and by the use of the speculum. The same may also be applicable to the pharynx. In the larynx ten- to twenty-per-cent. solution should be used. Sequesters, after they have been loosened, may be surgically removed.

#### *SOME POINTS IN THE TREATMENT OF BRONCHITIS BY DRUGS.*

D. J. LEECH, of Manchester, contributes an article on this subject to the *Practitioner* for May, 1898. He thinks that it may seem almost superfluous to write anything in the *Practitioner* concerning the treatment of bronchitis; it is so common an ailment that almost every practitioner has a large experience of the methods of dealing with it. But the writer has noticed considerable differences in the manner in which bronchitis is treated by medical men, and he thinks there are some points to which attention may with advantage be called—more, however, with regard to the manner in which drugs are given than with regard to the drugs themselves.

In acute bronchitis of adults a combination of acetate of ammonium, spirit of nitrous ether, and ipecacuanha or antimony is commonly used, and no better combination can be employed. But the writer holds that an error is often made with regard to the dose of two of these substances. The quantity of acetate of ammonium ordered is usually too small. The author commonly finds an ounce or an ounce and a half of solution of ammonium acetate ordered in an eight ounce mixture, an ounce of which is to be given every four hours. Now the writer would not say that doses of a drachm to a drachm and a half of solution of acetate of ammonium have no effect, but he is quite sure they are too small to be of value where the definite action of the drug is required. In the Pharmacopœia the dose of liquor ammonii acetatis is given as two to six drachms, and in this the Pharmacopœia is right. The writer has not found less than two drachms act on the skin or give the general relief which often results from a larger dose in the early stage of acute bronchitis. He believes it is better to begin with doses of three drachms, and to increase the amount to six drachms if the skin does not act freely. Marked relief to the breathing often, though by no means always, accompanies the diaphoresis.

Spiritus ætheris nitrosi, too, is very commonly given in doses too small to be of value. The writer has often seen prescriptions for acute bronchitis in which this drug has been ordered in doses of fifteen to twenty minims. It is not probable that such doses have any influence on the course of the ailment. Spirit of nitrous ether may possibly act in half-drachm doses, but in doses of a drachm to two drachms, especially when repeated at short intervals, it has commonly a very distinct effect as a diaphoretic. He believes it sometimes relieves the respiratory troubles by exercising influence on the bronchi and the vessels of the lung, for the ethyl nitrite of the spirit is capable of relaxing the bronchial muscles and dilating the lung vessels; but specimens of spirit of nitre often vary considerably in the quantity of nitrite contained. The author is inclined to suspect that the spirit of nitre in many surgeries is almost devoid of the active ingredient, for this is apt to decompose when the drug is long kept. It must be borne in mind that drachm doses of spirit of nitre occasionally give rise to eructations, and that there are some people who cannot take it in these doses without great discomfort. There is an interesting point in connection with the spirit of nitre which is worthy of notice. Mixed with water it rapidly decomposes, but in the presence of acetate of ammonium this decomposition is rendered slower. He suspects that it was partly on this account that practitioners in early times found it advantageous to combine acetate of ammonium and spirit of nitre in the production of the "febrifuge julep," which was once so largely used in the treatment of all febrile ailments. Both ammonium acetate and spirit of nitrous ether are largely used, without any clear idea as to the curative influence they are likely to exert, and under these circumstances the smallness of the dose does not matter; but in acute bronchitis, where a definite action is desirable, both drugs should be given in such quantities as are likely to quickly produce the desired effect.

In young children attacked with acute bronchitis, where the temperature runs high and a few scattered rhonchi over the lungs foreshadow further troubles, the writer has seen more advantage from giving antipyrin than from acetate of ammonium. After a five-grain dose to a young child five or six years of age profuse perspiration followed by a very marked improvement often occurs.

The author has often tried to determine

the comparative value of ipecacuanha and small doses of antimony in acute bronchitis. It seems to him that antimony in doses of one-twentieth of a grain is of most service where there are abundant small basic moist sounds and the breathing is oppressed; whilst where there are dry rhonchi all over the chest, with irritable cough, ipecacuanha is more useful than antimony. But he would not like to assert this confidently.

In cases of chronic bronchitis, ammonia, senega, squill and ipecacuanha are the drugs most commonly used, digitalis and strychnine being given when there is evidence of failing or defective cardiac or respiratory organs. Though the writer has much faith in carbonate of ammonium, he believes it often fails to benefit a patient owing to the manner in which it is given. He not infrequently finds patients suffering from severe chronic bronchitis taking three to five grains of ammonium carbonate, or ten to twenty minims of aromatic spirit of ammonia, every four hours. Such small doses probably exercise a beneficial influence on the stomach, by their carminative and antacid action, but he has never been able to satisfy himself that any influence on the circulatory and respiratory organs is produced by them. Such a dose as three grains of carbonate of ammonium must when taken into the stomach be rapidly converted into a chloride, and often five grains given at intervals of several hours can leave little margin for such absorption of ammonia as shall benefit the chest organs. It does not seem likely that doses of ten to twenty drops of aromatic ammonia, given at long intervals, can produce any other than carminative effects. On the other hand, he has seen ten grains of carbonate of ammonia, given every hour or two, cause distinct quickening and increased strength of the pulse. It is not so easy to determine the effect of ammonium carbonate on the respiratory organs; nevertheless, he thinks he has observed a favorable influence, the respiration being deepened and the expectoration more easily raised. Ammonia is very diffusible, and is doubtless quickly absorbed. There is every reason to believe that it is rapidly changed and excreted. It seems to Leech, therefore, that we can hardly expect that three to five grains of carbonate of ammonium, given at intervals of four hours, will exert any curative influence where it is necessary to stimulate the respiratory center and promote expectoration in a serious case of chronic bronchitis. To produce the effect which we desire

from carbonate of ammonium it should be given at short intervals. The drugs with which ammonia is frequently combined—squill, senega, etc.—are not advantageously given at very frequent intervals; moreover, the combination of ammonia with these drugs results in an unpleasant mixture, the nauseous taste of which is not easily concealed.

The most effective and convenient method of giving ammonium carbonate in chronic bronchitis is to dissolve it in water and give the solution in milk. If sixty grains be dissolved in six ounces of water, a tablespoonful (five grains of the carbonate) can be given every hour or two, according to the nature of the case, in the milk which is taken by the patient. A tablespoonful of such a mixture can be added to four ounces of milk—not, indeed, without making its presence perceptible, but without giving the milk a taste to which the patient will object. Indeed, many patients seem singularly insusceptible to the presence of carbonate of ammonium, and it is often possible to put five grains of carbonate of ammonium to two ounces of milk without any objection being raised. This method of giving ammonium carbonate in milk is specially advantageous when we wish to give strychnine as well as expectorants, for the addition of carbonate of ammonium to a mixture containing strychnine tends to throw down the alkaloid. The writer also points out that the presence of ammonium carbonate in the milk is advantageous because of its antacid effects, and in some cases milk agrees best when the ammonium carbonate is present. Aromatic spirit of ammonia cannot be well given with milk; the mixture is not agreeable.

One advantage of separating the administration of carbonate of ammonium from that of the other drugs is that we can give the latter beneficially without thereby losing the good effect that may be obtained from carbonate of ammonium. Senega and squill given at short intervals keep the stomach in a constant state of irritation. Senega is a somewhat remarkable drug. Nothing we know as to its active constituents enables us to understand how it produces expectorant effects. Its activity seems to depend on the presence of senegin, one of the saponin substances. Now saponins, as far as we know, are only absorbed from the stomach with the greatest difficulty; in fact, we have no proof yet that they are absorbed at all from the healthy stomach. Senega has maintained its reputation as an expectorant for so long a time that

we can hardly doubt it must have some value. It may, perhaps, act through its influence on the stomach, on the mucous membrane of which it acts as a distinct irritant, its effect being somewhat prolonged. Because of its irritating effect it is undesirable to give this drug at intervals of less than four hours.

The efficacy of squill in bronchitis is much questioned, especially on the Continent, where this drug is looked upon rather as a cardiac tonic than as an expectorant. But the writer feels satisfied that he is right in considering the latter property as the more important. He believes it is useful in all forms of chronic bronchitis, both in the early and late stages. When there is much dyspnea, however, and evidence of accumulation in the bronchial tubes, he is inclined to think that ipecacuanha is of more service if given in large doses. But these doses should not be very often repeated. He has not seen the benefit he has expected from continued small doses. It is wonderful what a large amount can sometimes be taken with advantage. A short time ago he saw a patient suffering from bronchitis, with intense dyspnea and cyanosis, which a variety of remedies had failed to relieve. He advised drachm doses of ipecacuanha wine every four hours. Next day he found the patient very much relieved and charmed with the medicine, which had caused some sickness, but not much. He found, however, that by mistake the wine had been administered in ounce doses.

In conclusion, in reference to the use of oxygen in inhalation, the author finds some objection to its use on the ground that it is not a really curative agent. This is true, but the inference that it is not worth giving is fallacious. It does remove cyanosis, and a continuous condition of cyanosis must be an evil. His feeling is that the inhalation of oxygen is generally commenced too late. He believes its early use prevents the advent of that pronounced cyanosis we so often see, and which, when it is once established, may be only slightly benefited by oxygen. It thus gives patients an additional chance of life, and furthermore, in most cases it gives marked relief. If we objected to giving drugs in ailments unless they had a direct curative influence our use of the pharmacopœial remedies would be very limited.

#### THE VOMITING OF PREGNANCY.

In the *American Journal of the Medical Sciences* for July, 1898, BACON considers this

important topic. As he remarks, the obstetrician is generally not called until the vomiting is quite severe. Prophylaxis here consists in preventing the graver forms. Advice can also be given for the benefit of future pregnancies. Such prophylactic management consists in the cure of anemia, caring for digestible foods, the prevention of constipation, the correction of retrodisplacements of the uterus, and the cure of adhesions of the uterus as far as possible by massage. Especial attention should be given to the mental condition of the patient. The cases are particularly bad where a child is not wanted. Those patients who have no self-control are the most serious cases.

It will be seen from this that treatment to prevent vomiting of pregnancy should begin with the birth of the girl, as suggested by Giles de la Tourette when speaking of hysteria. Like the prophylaxis in hysteria, the entire education of the child is important. Later, the masterful but kind bearing of the obstetrician is one of his most important aids. Rules of hygiene are especially important; regular eating and bathing, proper clothing, suitable exercise, enough sleep, and massage, if necessary, are all to be attended to. Often account should be taken of the reading and amusements of the patient.

The hygiene and general management, such as described in prophylaxis, are here about all that is needed. A proper condition of the bowels must be secured by the use of fruit, saline laxatives, enemata, and abdominal massage. The patient should take a cup of hot milk half an hour before arising in the morning. These measures will, in the majority of cases, prove all that is needed and a very great help.

In the treatment of hyperemesis gravidarum, except the extreme cases, the indications are: first, to allay excessive irritability of the nervous centers; second, combat the neuropathic condition, hysteria, by strengthening the will; third, remove the source of peripheral irritation.

The abnormal irritability of the central nervous system, which especially interests us, may be due to the deranged nutrition or to intoxication. In any case it is best allayed by providing a steady circulation of the blood with an equable blood-pressure, and good elimination by the intestinal and renal emunctories.

For maintaining a proper intracranial circulation the horizontal position is necessary, and this measure alone is the most important

of all things in treating the vomiting of pregnancy, as it is in the allied condition of seasickness. The position must be constantly and persistently maintained. It is often desirable to have the head lower than the feet. All nourishment must be given without raising the head. During vomiting the patient must be turned on the side, and on no account be raised. These details are so important, and yet so often neglected, that they must be emphasized and often repeated. Absolute rest in the horizontal position also serves another important purpose, viz., it insures against unnecessary loss of strength and vital energy. In extreme cases the dangerous symptoms and the fatal results are from inanition. When there is no fresh supply of food the body has a limited store of energy, and when the usable amount, which comprises less than one-half the body weight, is consumed the patient must die; hence it becomes very important to restrict the amount of energy consumed and avoid all waste from unnecessary movements until the possibility of a new supply is established. Just as a starving person can live longer if he remains absolutely quiet than if he makes violent muscular exertion, so a vomiting gravida conserves her vital energy by remaining in the horizontal position.

Other ways of maintaining a normal circulation consist: (a) in stimulating the cutaneous capillary circulation by topical applications; (b) in hypodermic injections of stimulants and vasomotor regulators; (c) injection into the diminished blood-current of artificial serum, either through the intestinal or subcutaneous route. Peripheral vascular stimulation secured by sinapisms or by the hot-water bag to the epigastrium or to the feet will, of course, not be neglected. Warm clothing to prevent cutaneous capillary obstruction, as well as to preserve the heat and energy of the body, will be looked after.

The use of drugs which act on the circulation is not unattended with risk, because of unpleasant action on other organs of the body. Nux vomica or strychnine may be one of the most valuable of these agents. Whether the bitter stomachics, including the recent and now popular orexinum basicum, so warmly recommended by Frommel, Rech, and others, act on the circulation or locally on the stomach is not, so far as the writer knows, determined.

The value of intravenous or subcutaneous injections of salt solution in raising the blood-pressure and stimulating the circulation is

now well established. In all obstetric cases he believes the subcutaneous injection may be substituted, with advantage, for the intravenous injection. In the hypodermic injection there is no danger of the introduction of air into the blood-vessels, and the constitutional symptoms of chill, etc., which often follow intravenous injections are absent; moreover, the former method is much simpler and can be carried out by any one, while the latter is a surgical operation of some difficulty.

The value of artificial serum in restoring the vascular pressure after severe hemorrhage, and thus counteracting its serious symptoms, has long been known. Its more recent use in sepsis has been based on the theory that it washes out the toxins in the blood. During its employment in these cases, however, its effect on the blood-pressure has been especially noticed. As is well known, in severe cases of sepsis the pulse becomes rapid and soft, and the patient suffers from symptoms of weakened circulation as well as intoxication. It is in this condition that the *lavage de sang* exhibits its best effects, so that Tuffier, one of the most enthusiastic and diligent employers of this method, suggests that its chief value may consist in its effect on the circulation instead of its supposed action as a means of washing the blood.

If the abnormal irritability of pregnancy be due to intoxication the need of thorough elimination is apparent. This elimination is secured in ordinary cases by careful attention to the skin by means of baths and proper clothing, by preventing constipation, and by furnishing the system as much water as possible to aid the renal excretion. In hyperemesis gravidarum the urine becomes very scant. Here the subcutaneous salt solution acts very promptly and efficiently, as will be seen from the cases that the writer reports.

Nerve sedatives can be used in hyperemesis gravidarum only with great caution. If morphine is used quite large quantities must be employed, and its effects have seemed to Bacon to be in general bad. Chloral has cured two cases in his hands that no other drug had helped.

As before stated, it has already been shown by Kaltenbach and Ahlfeld, and many others, that the neuropathic condition is a very common and important element in the causation of hyperemesis gravidarum, and must be taken account of in its management. While it cannot be admitted that hysteria is the sole cause of the disease, it is very essen-

tial to remember that it has an influence in many cases where, upon superficial observation, it would not be suspected, and that in other cases where no true hysteria exists some neuropathic condition, inherited or acquired, is one of the causative factors to be reckoned with. Hence the entire examination and treatment should proceed with this fact in view, in order that the proper psychical influences necessary to a successful control of a neuropathic patient may be obtained. In the management of these hysterical cases it is often best for the obstetrician to plainly inform the patient that the control of the vomiting is possible by an exercise of the will, and insist that she make the effort. Chazan reports a serious case to which he was called to induce abortion, which he successfully managed in this way. In many cases suggestion has been employed. Terrien reports a cure from the suggestion that the six-weeks' fetus had been removed, showing the patient a flake of mucus from the vagina. Doleris reports three cases cured by electricity when no current existed. These cases might be multiplied from the literature, but they are sufficient to show the possibilities of this method of management. It is also probable that many cases reported cured by the various methods of uterine treatment, by stomach lavage, by electricity, etc., are cases of cure by suggestion. Muret reports a cure which he attributed to suggestion after one lavage. As his patient had suffered from gastritis before pregnancy, it might not be possible to ignore the local effect of the treatment. It is, however, very likely that many of the cures from Copeman's dilatation of the cervix, from cauterizing the external os uteri with nitrate of silver, from the use of electricity, etc., are due simply to suggestion. Hence, in planning the course of treatment of a case of hyperemesis gravidarum it is very important to examine the patient very carefully to determine the presence of a hereditary tendency to hysteria, and to search for hysterical stigmata. Having found a neuropathic element, we should not neglect the well-established principle of treatment of hysterical patients. The most important measure is separation from friends and relatives. In these cases they form the worst possible nurses. Let the patient be isolated under the care of an intelligent nurse experienced in these cases, and be subjected to a regimen consisting of frequent feedings, massage, baths, etc. Such a course does not overlook the possibility of a complication

with some reflex disturbance from a peripheral irritation, which should, of course, be attended to.

If the examination has shown the presence of a peripheral irritation, either as the only recognized cause of the vomiting or as a complicating factor with hysteria, the treatment indicated is the removal of the irritation. One should not forget that pathological conditions in the gastro-intestinal tract may be a source of reflex vomiting. Physical examination of the abdomen will often reveal the presence of hard fecal masses in the ascending or descending colon, or in both. Our first effort will naturally be to remove them by large enemata, combined with massage. A number of cases have been reported where cancer, or stricture of the pylorus, or phlegmonous gastritis, has been found. Yeast cells are often abundant. In pathological conditions lavage is indicated. In a case the writer saw the stomach was the seat of excruciating pain, which had led the patient to take large doses of morphine. The author is inclined to regard this pain as a hyperesthetical stigma of hysteria. For such a case a local ice-bag is indicated.

When a pathological condition is found in the pelvis it should be corrected if possible; a retroflexed uterus should be replaced and held in place by a pessary. But little can be done for adhesions of the uterus to neighboring organs if first discovered in pregnancy. An eroded os can be touched with silver nitrate, more for the moral effect on the patient than for its use in curing the lesion. Copeman's dilatation should be used with great care, if at all, with the same object in view.

It has already been suggested that the congestion of the pelvic and splanchnic area veins may not only be an important cause of disturbance of the medullary centers, but also act as a source of powerful reflex irritation. In this case any measure already suggested to relieve the circulation will tend to relieve this congestion. In addition to these measures, the application of an ice-bag over the hypogastrium is worthy of trial.

Under the plan of treatment thus outlined most cases that have not advanced to the last stages of starvation can be controlled. It now becomes necessary to consider those cases in imminent danger of death from inanition, and to discuss the frequently employed procedure, the induction of abortion or miscarriage.

The results of abortion are not encouraging. Cohnstein's statistics embrace 200 cases, in only forty per cent. of which did vomiting cease after abortion. The death-rate is very high. Abortion is generally performed so late that it adds much to the danger of the patient, and if done early it is probably unnecessary. The writer adds three fatal cases where abortion failed to check vomiting and probably aided materially in the fatal issue. The first case was complicated with sepsis from the bladder, and, perhaps, should hardly be classed with the other cases, but for its bearing on the causation it is included.

#### *SOME NOTES ON ABORTION AND ITS MANAGEMENT.*

Under this heading we find in the *Intercolonial Journal of Australia* of March 30, 1898, a paper by ADAM. Notwithstanding all the ills that followed on the expectant treatment of the past, he is rather inclined to the opinion that the increase in our armamentarium, and the confidence, begotten no doubt by experience, with which we can handle the uterine cavity with comparative safety, has made us overready to interfere and neglect the *vis medicatrix*. By this is meant that the temptation to get the abortion over as soon as possible makes us use the curette and clear out the uterus in all cases, and as soon as possible. But Adam pleads for an intelligent expectant treatment—a delay until Nature has made her effort to complete the detachment of the ovum from the uterus, provided always there are no untoward signs. He does not subscribe to the view that curettage of the uterine cavity is advisable in all, or at all events most, cases of abortion. But the opinion is gaining ground that very many cases of abortion are injuriously affected by the indiscriminate use of the curette. The argument that abortion is a pathological process, and therefore there must be a diseased endometrium, which should be removed, does not seem to be sound.

The prime agent in the management of abortion is rest. When signs of impending abortion appear, the patient should be sent to bed, and should remain there absolutely until she has convalesced. As long as there are no symptoms of anything going wrong, such as hemorrhage or foul-smelling discharge, rise of temperature or pulse, it is only necessary to keep the patient at rest, and allow the ovum to separate in its own

good time. Should there be hemorrhage in an early abortion, and the case seen before separation of the ovum has taken place, it is an excellent plan after cleansing the vagina thoroughly to insert into the cervical canal a strip of iodoform gauze, packing it fairly tightly, and then to pack the vaginal roof with similar strips, leaving them from twelve to twenty-four hours in position. On their removal, the vaginal roof will be found nice and clean, with the cervix well dilated, and in many cases the ovum will be found quite separated and free. If it is not, its removal is greatly facilitated by having the canal dilated. In the past, before we ventured to thrust gauze or anything else into the uterus, the writer frequently made it a practice to tamponade the vagina, and although the sterilization of the vagina was necessarily imperfect, the results were excellent.

The routine administration of drugs, such as ergot, quinine, or Indian hemp, cannot be too strongly deprecated. Ergot, if it has any effect at all, must render the uterus in such a condition of tonic contraction that any subsequent procedures will be hindered, and as for quinine or cannabis indica having any effective ecboic action, Adam has doubts. But it is quite another thing to give such drugs after the contents of the uterus have been expelled. Then their effect on the vessels and uterine involution is marked. Perhaps one of the best combinations for the purpose is chlorate of potassium with ergot; another useful prescription is the stock one at the Women's Hospital, known as the Q. E. D. mixture—quinine, ergot, and digitalis. Such treatment quite suffices for an ordinary abortion; but in those cases where hemorrhage has been going on for some time, or where decomposition of the uterine contents is threatening, the uterus must be evacuated without delay.

Here it is that curettage has its legitimate field of operation. The patient should be anesthetized and placed on a table opposite a good light, and the cervix well exposed to view. If the cervix is not already well dilated, it should be carefully opened up, and the uterine canal gently and carefully curetted. The physician should be sure to examine all the scrapings, to see that the whole of the ovum has been removed, for the writer has known quite large pieces to be left behind sufficient to nullify the purpose of the operation. The uterus is then irrigated with sterilized water, or a weak solution of lysol, and then packed with iodoform gauze.

The operation is simple enough, but it has its dangers, and should not be lightly undertaken. Chief amongst the risks is the conveying of sepsis, although it would hardly be thought so in these days of asepsis. Another risk is the tearing of the uterus during dilatation, and of perforating it with the curette. The conditions of the case favor these accidents, for the uterus is soft and friable, and this is especially so when decomposition of the uterine contents has taken place. So easily may the uterus be perforated under such conditions that the writer has seen it done, and the operator was not aware of it until he hooked down with his curette a piece of intestine.

One more caution before resorting to the curette. After the patient is anesthetized, make a thorough exploration of the pelvis bimanually in order to see that there are no other diseased conditions, such as a pyosalpinx on one side, or a cystic tumor of some sort. For the writer has known patients to die from acute peritonitis after curettage from, apparently, a want of care in this respect.

#### NUCLEIN IN MALARIA.

The earnest student of medicine is continually surprised at the number of topics, thought settled for all time, which spring up with almost every step of progress. Especially is this true of the malarial fevers. The vast and delightful vista of study for microscopists opened up by the discoveries of Laveran, Marchiafava, Osler, Hewetson and others succeeded largely in ruling out many disorders formerly classified as of paludal origin. One could no longer be justified in assigning anomalous symptoms and disorders to that immense class vaguely termed "a touch of the malaria." With our more accurate means of diagnosis came corresponding strides in therapeutics, as has always been the case, especially during the last century, with pathological progress. Those poor unfortunates who have successfully resisted many physicians and methods of treatment are no longer saturated with cinchona and its derivatives.

Interesting observations have been made as to the behavior of this disease during the instigation of treatment, observations the result of which brought forth the initial sentence of this article. So many cases responded so readily and quickly to quinine, so beneficent and lasting were the effects obtained by this drug, that the dictum, corrob-

orated by the highest authority, was spread broadcast, that "a fever not responding to quinine was not malarial." It appeared as though "the final word" had been spoken, so meekly was this law accepted by the profession. But again it was only the ominous silence that often precedes the storm. Fortunately for science there are always in every branch those sturdy thinkers who accept nothing but what they themselves have personally proven. Shortly there arose a small cloud in the clear sky of malarial diseases, which has been gradually assuming such large proportions that the storm it foretells will inevitably cause material change in our ideas of this peculiar disease.

The first observations of ague in this country, and those upon which the law above referred to is based, were made mainly by Northern men, or, in other words, in a latitude where the most bizarre phases of the disease are rarely seen—those of the estivo-autumnal parasite. As regards the tertian and quartan forms of the plasmodium, continual study but adds proof to the dictum of Osler, that "any fever that resists the action of quinine is not malarial." Osler's researches and those of his associates were mainly made on the study of the two latter types; in those cases of estivo-autumnal variety which did come to their notice, it must not be forgotten that the very change of climate which their patients enjoyed may in large measure have contributed to the good results reported. However that may have been, the fact remains that many cases, estivo-autumnal in type, especially those in the more southern latitudes, cases in which the diagnosis has been absolutely proven by the presence of crescents and ovoids in the blood, have not been benefited by quinine or its derivatives, administered in small or large doses, in solid or liquid form, by mouth, rectum, or hypodermically, though it must be confessed that the best results in persistent cases have been obtained by the latter method of administration. Reports of such cases have appeared so frequently in medical literature that their significance can no longer be ignored. The most recent article on the subject appeared in the *Medical Record* of February 7 in a masterly article by Beverly Robinson. The practical result of all this is that necessarily more or less marked changes in therapeutics appear, for the active physician cannot await the decision of scientific discussion when his patients are clamoring for relief from their symptoms. Accordingly, as quinine seemed unable to perform

the allotted task, other drugs were tried with more or less indifferent results.

It is the usual fate with every new preparation that appears that there are always some enthusiasts who, carried away by partial or a few successes, laud their favorite of the hour to the skies. They rush rapidly and eagerly into print, anxious to put themselves on record among the first. Unfortunately, on the inevitable failures that follow fair and impartial trials of so many of our preparations they are silent, not wishing to refute their former lavish praises even for the advance of medical science. It is no wonder that careful and conservative men are chary about using new drugs. The stamp of universal approval and of age is necessary to such as a plea for recognition. Adherents there have been and yet are to methyl blue, arsenic, iron, strychnia arsenate. Among later remedies, nuclein is receiving very favorable comment. This substance is extracted from animal membranes, the spleen, testes, the thyroid, or perhaps more readily obtained from yeast after the method of Vaughan. It may be administered hypodermically or in tablet form, each tablet corresponding to one drop of nuclein.

The germicidal action of the blood has been known for a considerable time. Further experimentation proved that this germicidal action was due to a substance, given the name of nuclein, which was furnished by the polymorphonuclear neutrophiles. Now in chronic wasting diseases, such as tuberculosis and chronic malaria, the blood, of course, deteriorates with the other body tissues. The function of the neutrophiles being thus impaired, less resistance is offered to invasion by micro-organisms. Remember the predisposing cause insisted upon in all infections—lessened physiological resistance from whatever cause. Theoretically, in our treatment, if we can bring the resistance of the blood to invasion to par, either by stimulating the neutrophiles to increased activity or by supplying artificially the substance needed to bring about a physiological resistance, an improvement or cure should result. As a theory all this sounds very plausible; practical trial by Wilson and others contributes instances of perfect cure in cases of undoubted malaria, which had proved intractable to quinine in large doses. Small doses of nuclein (one drop every two or three hours) caused a prompt disappearance of the cachexia, migraine, gastro-intestinal disturbances, hematuria, general depression, and

other so-called malarial symptoms under which the patients were suffering. In view of the resistance of a certain percentage of cases of malaria to cinchona treatment, such reports are, to say the least, interesting, and demand a fair trial for the remedy to prove its efficacy.—*Cincinnati Lancet-Clinic*, April 30, 1898.

#### TREATMENT OF FRACTURES.

The *International Journal of Surgery* in a recent issue prints the opinions of that well known practical surgeon, Dr. ESTES, on this important topic. In regard to fractures of the humerus he points out that the part of the bone most commonly fractured, in his experience, depends to a great extent upon the age of the injured person. Adults seem to have the fractures located most frequently near the surgical neck, and in the shaft of the bone (in the diaphysis), whereas children show a larger percentage of fractures at or near the junction of the epiphyses. Fractures about the condyles are especially common in children.

*Intracapsular Fractures of the Humerus.*—The head of the humerus is rarely fractured except by direct violence. In civil practise, therefore, the intracapsular fractures may be regarded as fractures of the anatomical neck. It is sometimes difficult to make a diagnosis of these fractures without the use of the fluoroscope. In using this instrument in children the epiphysal cartilaginous union is apt to lead to a wrong conclusion, as it is much more permeable to the  $x$ -ray than the bony tissues. This must be borne in mind in these examinations therefore. Eliminating this source of error, the fluoroscope is an exceedingly valuable aid in diagnosing fractures of the upper end of the humerus. As it is well known that inspection of the fragments may occur after fractures here, one does not like to employ force or too extended manipulation in order to elicit crepitus. In case of doubt it is safer to treat the injury as one of fracture.

The fractures of the anatomical neck are usually transverse fractures. When impaction occurs, there may be, and indeed usually is, also a longitudinal fracture, a splitting of the tubercles; so the fracture becomes extracapsular in these cases.

When the head is broken off transversely at the anatomical neck the expectation of reunion is not very sure; the author has found that it does take place in most of the

cases, however. He has not yet had necrosis of the detached head occur. He thinks he has seen a few cases in which there was atrophy or absorption of the head after this fracture.

The treatment of intracapsular fractures requires, first, careful manipulation to restore the head to its proper place on the shaft, and then careful placing of the head against the glenoid cavity, so that this counter-pressure may hold the fragments together. A firm axillary pad is needed to prevent the end of the shaft slipping inwards: a well fitting shoulder-cap of leather, or silicate of sodium (plaster of Paris is so friable that unless the cap be made very thick it will crack and crumble, hence it is not so useful as water-glass at this region), or wood fiber, or strong felt should be adapted, and then the whole extremity bandaged from the fingers upward to prevent edema of the fingers and forearm; the elbow should be supported by a bandage which also confines it to the side a little posterior to the axillary line. The author is opposed to early passive movements of the shoulder-joint after these fractures. He thinks at least four weeks should be allowed before any but the most careful and guarded movement be permitted. On the other hand, frequent passive movements of the elbow, wrist and fingers should be employed and begun early to prevent stiffening of these joints.

The immobilization and bandages should be continued for at least four weeks. Then the shoulder-cap may be taken away, and gentle massage and very careful passive movements employed daily, always followed by a fresh bandage, and fixation of the elbow for another two weeks, then a gradual freeing of the elbow, and finally the shoulder may be freed and voluntary movements begun in about eight weeks.

Function is usually restored very slowly after these fractures, especially in middle-aged and old people. The capsule is commonly injured and the bicipital groove roughened; the result is that for weeks after the fracture seems united there is an aching pain, worse at night and when a storm approaches; and a trophoneurosis is apt to result on account of the irritation of the circumflex nerve branches. This condition is very discouraging to the patient and requires persistent treatment by massage, galvanism, and passive movements. The author has also found that the correction of any possible tendency to lithiasis by a graduated alkaline

treatment is of great service when the patient has previously been subject to rheumatism or gout.

#### *Fractures of the Tubercles of the Humerus.*

—As separate and uncomplicated injuries—that is, when not a feature of general comminution of the upper end of the humerus—fractures of the tuberosities of the humerus are rare. The author has seen one case of fracture of the greater tubercle. The greater tubercle is the one generally fractured in these rare cases, and probably muscular contractions cause the injury when not produced by direct violence. The fracture is longitudinal and there is considerable separation, the detached fragment being drawn outwards and upwards by the supra- and infra-spinatus and teres minor muscles. It is very difficult to keep this fragment in place. Relaxation of the muscles by drawing the shoulder backwards should be secured. Then by careful palpation find the small fragment of bone, and push it forward to its place; then hold it in place by a firm compress laid behind and over it, and held firmly down by a strip of adhesive plaster laid on from behind forward. A bandage should then be employed to keep the shoulder back and immobilize the shoulder and arm.

The union will probably be fibrous in adults. The functions of the shoulder-joint are materially lessened; strength and motion are usually impaired for several months. The bandage immobilization should be continued for at least six weeks, then graduated passive movements and massage should be employed. After this a regulated series of active movements in the way at first of "resistance movements," and then light gymnastic exercise, will assist in restoring the strength and activity of the injured shoulder.

Atrophy of the suprascapular muscles sometimes occur. Dr. Hall sums up the result of his treatment in his paper, read before the twenty-eighth annual meeting of the Medical Association of Central New York, October 15, 1895, as follows:

"The result of this case, three months after the receipt of the injury, is briefly stated as follows: Fibrous union, as shown by the mobility of the fragment and the presence of crepitus, has taken place. The humerus is not shortened. There is some inward rotation of the arm, in consequence of which the shoulder-width is increased three-eighths of an inch. The joint function is impaired, motion being considerably restricted

and quite painful. The scapular muscles are wasted, notably so in the infra-spinatus, its extent being shown by the marked depression of the scapular surface. The power of active voluntary motion is diminished. Particularly true is this of outward rotation, which is feebly performed. Some improvement of the present condition will unquestionably follow, and, upon the whole, the probable result will be better in this instance than is usual with cases occurring at an advanced period of life."

*Fractures of the Surgical Neck and Upper End of the Shaft of the Humerus.*—For practical purposes the fractures of the surgical neck and fractures of the upper end of the shaft of the humerus may be understood to mean fractures of the upper third of the shaft. These fractures are the most common ones met with in subjects past maturity. They are usually oblique. If the fracture is immediately below the tuberosities the difficulty will be in preventing the scapular muscles rotating the upper fragment outward. The lower fragment, though drawn upward and inward for some distance, as a rule occasions very little difficulty after it has been thoroughly reduced. Fractures lower down between the attachments of the latissimus dorsi, the greater pectoral, and the deltoid are difficult sometimes, also, on account of rotation and the tilting upward of the fragment.

In reducing these fractures, after extension in the line of deformity (which will be slightly outward, the elbow abducted) has brought the end of the lower fragment in apposition with the rim of the upper fragment, the elbow should be carried to the side and held within an inch or two of the side of the chest, and the arm rotated outward, so that the hand shall be in a supinated position. While an assistant holds the forearm and elbow in this position, the surgeon should attempt by pressure directly over the upper fragment and by drawing the shoulder backward to bring the upper fragment into accurate apposition with the lower. A strip of adhesive plaster about seven or eight centimeters (three inches) broad, laid on from before backwards, beginning at the groove between the pectoral and deltoid muscles and passing over the head and tuberosities of the bone, then fastened to the back and opposite side, will assist in maintaining this apposition. An axillary pad will be necessary; this ought to be of some aseptic absorbent material, such as sterile absorbent cotton covered with sterile gauze, and should be laid

in place after the axillary space shall have been thoroughly bathed with soap and water, and then with alcohol. A molded shoulder-cap of leather, wood fiber, or thick felt well padded, should be firmly bandaged in place, the arm immobilized while the extension is kept up at the elbow, and this extension preserved by turns of the bandage from before backwards and downwards across and around the lumbar region. If the elbow is free, the author has found the patient usually moves it too much; it should not be supported in the sense of being pushed upwards. He thinks it best to immobilize it and keep extension on it as much as necessary. He has not found plaster of Paris a good material for splinting fractures of the upper part of the humerus nor about the shoulder-joint. It is apt to crack and crumble and is too cumbersome.

The matter of keeping the elbow near the side while reducing and holding these fractures is of great importance. For this reason it is very difficult to set these fractures properly while the patient is in a recumbent position. He should be sitting, or if he can, standing upright. Anesthesia in reducing these fractures should not be used, therefore. Happily it is rarely required. In a recent case the author found so much pressure was necessary to hold the fragment down that he employed a segmented Levis' shoulder-cap, one which could be placed at various angles; in this way graduating pressure was employed and controlled the tilting.

#### *THE SURGICAL OCCLUSION OF THE CEREBRAL SINUSES.*

STRATTON (*Annals of Surgery*, August, 1898), stimulated thereto by difficulties encountered in the removal of a large brain sarcoma which had invaded the longitudinal sinus, contributes a timely and excellent article on surgical occlusion of the sinuses. He says that the latest work from the American press, dealing quite thoroughly and authoritatively with the subject of cerebral surgery, unqualifiedly asserts with reference to the sinuses that "when necessary to attack them they may be ligated and divided." This statement, together with the declaration, by the same author, that clamps may be used instead of ligatures, without reference in either case to the necessity of adopting any other mode of procedure than would be necessary in dealing with a vein with its easily collapsible walls, is certainly mislead-

ing. Yet the statements of that author give but the same impression which is conveyed by the study of the writings of others who have practised or upheld the use of the ligature. To follow at least their implied method is to invite defeat and subject the patient to grave danger.

Even when the overlying portion of the calvarium has been successfully removed, the determination of the location of the borders of either the longitudinal or lateral sinuses, to which this paper primarily refers, is difficult or even impossible, unless by suitable incisions in the dura the sense of sight and even touch is allowed a freer range to establish their situation. And without that knowledge, to blindly pass the ligature, even if we are not to consider the probable damage to the cerebral tissues which that procedure entails, and are so fortunate as neither to puncture the sinus nor wound a pial vessel, and include within the ligature only the proper amount of the dura beyond either border of the sinus, there still remains two dangers before occlusion can be effected. The *sinus may be lacerated* as the ligature is drawn taut, with the result of having a troublesome or an appalling hemorrhage, *or pressure upon the cerebral substance may be produced* by increasing the tension of the dura and depressing it below its normal position. The possibility of both of these disadvantages exists by reason of the firmness and elasticity of the dura mater.

If neither of them is to result, in case relaxation of that membrane does not exist as one of the conditions inducing operation, or has not been effected by the surgeon, as the ligature is drawn tight the dura or falx—or the tentorium, if the lateral sinus is being operated upon—must tear sufficiently and in such a direction as to permit easy and safe approximation of its walls. That they would do so to such an extent as to allow no material degree of tension of the dura, or in such a direction as not to involve the walls of the sinus, are chances so small that the risk is entirely too great to be assumed.

Of course, coincidentally with the tightening of the ligature the dura could be suitably incised, and thereby cerebral pressure and laceration of the sinus avoided; and even after tying the ligature, incisions of the dura would relieve pressure upon the cortex of that membrane. But the advantages of making the incisions in the dura prior to passing the ligature are so great that, since that tissue is to be incised, it should be done at such a

stage of the operation as will permit advantage to be taken of it in the avoidance of the danger of wounding the cortex, sinus, or the veins entering it.

The possibility of puncturing the pial vessels in the passing of the ligature should be especially emphasized. It amounts to a degree of danger so great as to forbid its performance without visual guidance. At their juncture with the sinus most of these veins are of considerable size, and in some of the pathologic conditions requiring operation may be much larger and more tortuous than they normally are, and their walls being extremely delicate make them easily susceptible to laceration. Nothing less than the cautious incision of the dura—except in children in whom this membrane is translucent—and the accurate placing of the ligature by the sense of sight will guarantee against a troublesome hemorrhage from this source. It would be possible for even a fatal subdural extravasation of blood to gradually take place without the operator's knowledge, unless the dura were incised to permit its discovery and prevention.

As far as relates to the control of hemorrhage, the ligature has been used with success a number of times. Ashhurst in 1885, in referring to wounds of the sinuses, states that "ligation has been occasionally practised." Kammerer in 1889 ligated the longitudinal sinus an inch or so above the torcular Herophili as a preliminary to the removal of a sarcoma involving the dura above the sinus. Park mentions ligation and even resection as legitimate procedures. Starr refers approvingly to tamponment, forceps pressure and suture of the sinus in case of hemorrhage, and Keen states that in the same condition "the sinus has been tied by two ligatures." But none of these writers, however, call attention to the unwarrantable degree of cortical pressure which the use of the ligature or clamp may entail.

Nor has the danger of laceration of the sinus during the tightening of the ligature apparently been sufficiently realized or emphasized. Macewan, however, in order to avoid that accident, recommends a method practically the same as that mentioned by Ashhurst, of securing occlusion by separating the outer wall of the sinus from the skull, and pressing it inward into the lumen of the sinus, and tamponing the intervening space. This seems to be a method especially adapted to the rapid relief of hemorrhage—and it is in this connection mentioned by

Ashhurst—rather than a procedure to entirely prevent it, and to be generally commended in deliberate surgical attack upon a sinus.

It can be advanced as a proper objection to this method of securing occlusion in formal resection the general impossibility of knowing prior to the time of operation the necessity of the destruction of the sinus or of estimating the extent to be excised, should that be found necessary; the borders of the bone opening will seldom be so located that this procedure could be adopted without sacrificing a greater extent of the sinus than would be required by a method permitting greater freedom of choice in locating the site of occlusion. In its bearing upon the subsequent establishment of the anastomotic circulation this is a matter of much importance.

The greater sense of security which other methods give will also cause this procedure to be followed in a comparatively small proportion of cases, other than for the relief of accidental hemorrhage.

The application of the clamp presumes almost necessarily the exposure of the sinus, and in effecting this it would generally happen that sufficient relaxation of the walls of the sinus to permit their easy approximation had been effected. If, however, this has not been provided for, danger of laceration of the sinus or brain-pressure would exist, as in the case of the use of ligature. The degree of the liability to bleeding is less, however, with the clamp, by reason of the greater width which it possesses, with consequently less likelihood existing of its tearing or cutting its way directly into the sinus as the ligature might do.

Providing the preliminary work of the surgeon has not caused sufficient relaxation of the dura, or it does not exist as the result of traumatism, formal incisions along at least two of the borders of the sinus are necessary to prevent the danger of hemorrhage or pressure; and while choice can be made of any two, those generally the most accessible and therefore the most easily and safely incised are the two superficial borders. However, it may possibly happen that the conditions of the operation will make the deep border sufficiently accessible to permit incision in that locality. Especially is this to be preferred in cases where it is unnecessary to remove both lateral walls of the sinus. By making incisions along the deep and one lateral border a tumor involving only the

wall on that side might, after effecting occlusion of the sinus, be removed by exsecting only the wall involved. If the small incision in the dura on the side opposite the growth, made to allow the safe application of the ligature by inspection, is accurately sutured before the ligature is tied, the dura on that side would be left intact. A decided advantage would thereby be gained.

Due consideration must be given to the important functions of the supporting membranes of the brain, and no incisions should be made of greater length than are absolutely necessary to accomplish the end sought. Long incisions are unjustifiable. Thus, if the falx, or tentorium, or even the dura in the neighborhood of either of these, is extensively incised, the proper relation which one portion of the brain should permanently bear to the other is destroyed. With change of position of the head the weight of one hemisphere would have to be sustained, in part at least, by the other, or the cerebellum would be unduly pressed upon, according to the site of the incisions. A small disturbance of the cerebral support and equilibrium would be associated with disturbances either troublesome or grave, according to the amount of disability existing in these membranes.

The advantage which properly constructed clamps possess over ligatures lies principally in the relative ease and speed with which they can be applied. Thus far their use has not been attended with hemorrhage upon removal, a fact to be accounted for by reason of the low degree of blood-pressure in the sinuses. However, experience in their use has not yet been so abundant as to disprove this to be a real danger, and if the patient's condition is such as to permit the cautious application of ligatures, their use is to be preferred.

If clamps are used, they are incorporated with the wound coverings and removed with the first change of dressings at the expiration of from one to three days. Nor do they by requiring an open wound interfere with union. As is well known, even when these wounds pursue an aseptic course, the free discharge of bloody serum requires drainage for several days at least, and the openings left for the clamps can be utilized for that purpose.

To prevent the failure of the establishment of the collateral circulation, the author would strongly urge that the following precautions be taken in deliberate operations for lesions, the symptoms of which suggest the possi-

bility of requiring destruction of a cerebral sinus:

1. Prevent excessive loss of blood by the application of the tourniquet firmly to the scalp, and prompt occlusion of bleeding points on its removal; also by rapid bone-section and tamponment of the resulting sulcus. Starr states that the method of preventing hemorrhage by the application of the tourniquet to the scalp is a failure, but the author's own experience has taught him its great value at least in certain cases. If much oozing of the blood occurs upon incising the dura, rapidly complete the necessary incisions by the assistance of a delicately grooved director and apply tampons. Avoid puncturing the pial vessels.

2. The bone and scalp flaps having been raised and hemorrhage stopped, conclude the operation at this stage according to the method advised by Park in operations on the brain in which there is danger of shock, by inserting between the edges of the scalp a layer of gauze to which an antiseptic ointment has been applied. In a week or two, when the effects of this stage of the operation have passed off, conclude the second stage.

If, however, the circulation of the patient lacks vigor, or if for any reason there is doubt as to the second stage being concluded without shock, in addition to the above make dural incisions necessary to permit the proper application of ligatures or clamps; apply these and partly close the lumen of the sinus with a view of performing gradual occlusion. This is to be effected by partially tightening the ligatures or closing the clamps about every second day, until, in the course of one or two weeks, the sinus is entirely occluded, and thus, by the time the patient's condition warrants the concluding part of the operation being performed, the collateral circulation will have been already established and the possibility of blood stasis and thrombosis reduced to a minimum.

The same circulatory conditions which would cause the method of gradual occlusion to be adopted as a part of the preliminary stage should induce its being followed in the secondary operation, should shock supervene at any time during its performance, or should pial veins, taking an important part in the anastomotic circulation, be accidentally injured or destroyed by the necessities of the operation. This would cause the concluding steps of the operation to be still further delayed, but however unde-

sirable and although attended with increased risks of sepsis is, in the author's opinion, under the circumstance named to be strongly commended.

3. During the performance of the final stage of the operation and after occlusion of the sinus, should extensive hemorrhage occur or should there be any tendency for the pulse to become soft, small or feeble, maintain a proper degree of blood-pressure by having an assistant perform at once intravenous saline transfusion—a vein having been previously exposed, should the necessity of this seem at all probable. Or Esmarch's bandages may be applied to the extremities, or the two procedures may be conjoined.

Further than this, prevent any tendency to shock by proper stimulation with alcohol, strychnine, etc., by operating rapidly and having all contingencies provided for and allowing only the least possible amount of the anesthetic to be administered.

4. Avoid especially injury to the veins of the pia mater, through which the blood-current is to be maintained after occlusion of the sinus is effected. This includes not only laceration or puncture, which would require ligation, but also all those procedures which tend to maintain the vitality of the parts locally and prevent hernia cerebri. Among these factors can be mentioned rigid aseptic technique, the avoidance of traumatism, and osteoplastic or heteroplastic operation on the skull. It can be readily seen that even a slight protrusion of the cortex beyond the level of the internal surface of the skull would occlude the lumen of any vein traversing its surface by compressing it against the border of the bone opening. Also the long-continued vomiting, and possibly even the cerebral pulsation which results from removal of the firm bony support to the brain, will, if the dura has been extensively incised, produce such a degree of traumatism of the delicate cortical substances as to induce not only a local cerebritis, but even softening and disorganization. A vein traversing such an area would be destroyed even if hernia cerebri did not cause its occlusion.

5. During and after the operation have the posture of the patient such as will maintain a proper degree of pressure within the cerebral blood-vessels and facilitate the flow of blood through the sinus and the vessels concerned in the anastomotic circulation. The head should be on a level with the body and the face directed upward.

6. If vomiting continues for any consider-

able period subsequent to the operation, administer salt solution per rectum, and thus assist in maintaining the fluidity and proper degree of pressure of the blood.

*PROTARGOL AS A SUBSTITUTE FOR NITRATE OF SILVER IN OPHTHALMIA NEONATORUM AND OTHER CONJUNCTIVAL DISEASES.*

CHENEY (*Boston Medical and Surgical Journal*, Aug. 25, 1898) states that during his recent four months' service at the Massachusetts Charitable Eye and Ear Infirmary he has used protargol in one hundred and thirty cases, and it seems to possess all the advantages of nitrate of silver and none of its disadvantages. The very slight degree of irritation which it causes, and in a large proportion of cases the almost complete absence of pain, are its chief points of recommendation. A ten-per-cent. solution causes rather less flushing of the eye and discomfort to the patient than a one-per-cent. solution of nitrate of silver. A two- or four-per-cent. solution can be used without cocaine and the irritation is not, as a rule, more than would be induced by a one-half grain to the ounce solution of zinc sulphate.

There have been an unusually large number of ophthalmia neonatorum cases this summer, and the author has used this remedy in twenty-five instances. In ten of these he has used protargol in the right eye and nitrate of silver in the left, in order that the results might be more accurately compared. A two- or four-per-cent. solution was used, more often the latter, and a one- or two-per-cent. solution of nitrate of silver. The silver was applied to the conjunctiva in the usual way with a camel's-hair brush and in some cases with absorbent cotton, while in a few cases a quarter dropper full of the solution was emptied over the conjunctiva. When applied with absorbent cotton, the cotton was used on the end of a probe and the protargol was sopped on the conjunctiva, not brushed roughly over it. The lesser degree of irritation in the protargol eye was usually very noticeable. There was not the profuse lacrimation and the eye would often be open in a minute or two after the application, while the nitrate of silver eye would be tightly closed. It was also observed that there was less tendency to the formation of a fibrinous coagulate, the grayish shreds of tissue and "false membranes" in the protar-

gol eyes. In regard to the rapidity of the decrease and duration of the discharge, there is such a variation in different cases and often in the eyes of individual cases that it is impossible to judge with any degree of certainty. The author states, however, that in this respect the two remedies rank about equal.

As a prophylactic, Dr. William L. Richardson, who has used protargol at the Lying-in Hospital, very kindly writes the author the following:

"Protargol (two-per-cent.) has been used in every baby's eyes at birth for about three months. None of the redness and swelling of the lids and none of the temporary secretion that immediately follows the use of nitrate of silver (one-per-cent.) have been observed. In the few cases of purulent ophthalmia that have been treated with protargol the length of the course of the disease has apparently only been slightly shortened, but the severity of the attack has been decidedly lessened. Whether this has been due to the protargol or not, we have been, during the three months it has been used, more successful in confining the infection to one eye."

The fact that nitrate of silver does cause more or less irritation has prevented its very general use as a prophylactic outside of lying-in hospitals. If protargol is as valuable, and it in all probability is, this objection is overcome, and it is to be hoped that it will be generally adopted in routine practice.

The author has had but two cases of gonorrheal ophthalmia in the adult this summer, and protargol was used in both. In the first the cornea was extensively infiltrated when the patient came in, and, as was to be expected, it perforated two days later. The second case was of less severity and made a rapid and satisfactory recovery.

In acute conjunctivitis protargol was used in fifty-three cases. Most of them recovered promptly, but perhaps not more rapidly than they might have under some of the other commonly used remedies. In a few cases recovery was slow and they seemed to do better under a collyrium of zinc sulphate and boric acid. It was generally prescribed in a one-half-per-cent. solution dropped into the eyes every three or four hours. In twenty-nine cases of chronic conjunctivitis it acted very favorably in some, in others it seemed to have no especial action one way or the other, and in one case it proved a decided irritant. In twelve cases of chronic granular

conjunctivitis a four-per-cent. solution was used, and in three or four cases a ten-per-cent. solution. It seemed as satisfactory in its results as silver nitrate and was certainly much more agreeable to the patient. It was also tried in ten cases of lacrimal obstruction with purulent secretion. In two or three cases where it was prescribed as a one-half-per-cent. collyrium, the discharge ceased entirely within a few days. In other cases where the discharge was profuse it was injected into the sac in a four- or ten-per-cent. solution. The discharge usually lessened, but perhaps not more rapidly than it would have done under various other remedies.

---

#### THE QUESTION OF THE CURABILITY OF CANCER OF THE BREAST.

J. COLLINS WARREN makes a valuable contribution to this subject in the *Boston Medical and Surgical Journal* of August 25, 1898. He says that of the tables given in his article, including seventy-two cases, covering an interval of fifteen years, they do not include all cases operated upon during that period, as the histories of many of the earlier ones could not be obtained, and many had to be thrown out, owing to imperfect pathological records. Of the seventy-two cases there are twenty-six known to be alive at the present time, and thirty-eight known to have died. Of the latter, there were, however, two cases in which death occurred of other diseases than cancer, and that too long after the danger limit had been passed. In other words, nearly half of the cases are known to be living today or to have died of other diseases than cancer.

Of the twenty-six living cases there are three who now have recurrence of the disease, and four who have had a recurrence but have remained well at the present time. We find that in the fifty cases in which recurrence took place there were thirty-four local recurrences and only eight in which the field of operation remained in a healthy condition.

Such statistics emphasize the importance of strict attention to the rules now laid down, namely, the removal of a large margin of the cutaneous covering of the breast, a careful deflection of the edges of the wound, removal of the subcutaneous fat for a considerable distance around the mammary gland, the removal of the pectoral muscles, and a minute and painstaking dissection around the sheath of the axillary vessels.

In only one of the successful cases was there a dissection of the supraclavicular glands.

In regard to the situation of the growth we find that in twenty-five cases no statement is made as to the locality. This leaves forty-seven cases. In thirteen of these the disease was found in the upper and outer quadrant; in the upper and inner quadrant in six cases; in the central region in six; in the upper hemisphere in five; in the lower and outer quadrant in five; in the outer hemisphere in three; in the inner hemisphere in one.

These figures show that the disease is more frequently found in the upper and outer quadrant than in any other quadrant, in the upper hemisphere more frequently than in the lower hemisphere, and in the outer hemisphere more frequently than in the inner hemisphere.

The periods during which recurrences are observed are also of value. In nine cases it was not possible to learn the date of recurrence, but of the other forty-one cases thirty-seven occurred during the first three years; of the remaining four cases two recurrences were found between three and four years, and two between five and nine years. One of these exceptionally late recurrences was a colloid cancer in which an axillary gland evidently had been overlooked. In the case in which a nodule was removed from the pectoral region nine years after the original operation, it seems reasonable to assume that a new infection had taken place in a para-mammary gland. The existence of these glands is now well recognized by anatomists, and the fact shows the importance of including all such adjacent gland tissue in the field of operation.

Taking the three years' limit as the gauge of success, there are seventeen such cases. Two of these are dead, one dying ten years after the operation of apoplexy, and one dying of sporadic cholera six years after the operation. Three of these have had recurrences, one in the axilla and two in the pectoral region. These nodules were removed, and the patients are now alive and well, one of them three years, one four years and one ten years after the last operation. Of the remaining twelve, the operation was performed in three cases over three years ago; in four cases over four years ago; in two cases over five years ago; in one over nine years ago; in one eleven years ago; and in one case over twelve years ago.

An analysis of the diagnosis in these seven-

teen cases shows that nine were reported to be cases of "cancer," six reported as cases of "scirrhus," one medullary cancer, and one colloid cancer.

The percentage of cures, or those which have passed the three years' limit in fifty-five cases, is 30.9 per cent.

In estimating these results it should be remembered that the operations extend over a period of fifteen years, and that the earlier operations do not compare with the later ones in thoroughness. They do, however, cover that period in which the axilla was dissected in all cases, but of the earlier operations not much more can be said than this.

If now we begin with January 1, 1893, and take in all those cases which come up to the three years' limit—that is, up to April, 1895, or just three years ago—we find twenty-two cases with eight cures, or a percentage of cures of 36.3 per cent.

Comparing these figures with those which are given in statistics collected by Dowd, we find 199 cases, with 71 cures, or 39.6 per cent.

This percentage seems remarkably high for so large a series, but it includes Rotter's series with 50 per cent., including only 15 cases, and Cheyne's with 57 per cent., including only 33 cases.

#### GUNSHOT INJURIES OF THE SPINE, WITH REPORT OF A CASE.

Under this title PREWITT presents a careful review of the subject in the *Annals of Surgery* for August, 1898. He concludes as follows:

It is the duty of the surgeon to advise immediate operation in all cases of gunshot wounds of the spine, provided the wound has involved the posterior or lateral parts of the spine at an accessible part; unless the condition of the patient is such as to indicate clearly that he is hopelessly stricken.

To wait to see whether Nature is competent to restore the damage is to wait until irreparable damage has been done in many cases—rapid degenerative changes, meningitis, and myelitis. The delay permits of the continuance of conditions, the removal of which is the purpose of the operation. These considerations apply with greater force, if possible, in gunshot injuries than in others.

The presence of complications due to penetration of the great cavities and injury of

the viscera will influence the question of operation, but not necessarily forbid it.

#### THE ABORTIVE TREATMENT OF ERY- SIPELAS.

Dr. LABIT (*Bulletin Général de Thérapeutique*, 1898, p. 540) recommends the use of a ten-per-cent. solution of iodol in colodion.

The affected area is thoroughly painted with this and the coat extended for an inch over the healthy skin. If the hairy scalp is invaded, it is first carefully shaved, then painted. That the iodine contained in the iodol is absorbed is shown by its appearance in the urine. Frequently within twenty-four hours all symptoms of the disease will disappear. It is not claimed that iodol is the only specific for the streptococcus of Fehleisen; doubtless other antiseptics can produce the same result. The pressure produced by the colodion and its penetration, carrying with it the remedy into the tissues, is important. The method is not painful, but, on the contrary, is anodyne. The results tend to show that at first the disease is local, and since this is so no general treatment has been employed. —*American Journal of the Medical Sciences*, August, 1898.

#### THE HERNIAS OF CHILDREN.

Dr. W. B. COLEY (*Archives of Pediatrics*, April, 1898) states that in upwards of 300 operations for hernia in children under fourteen years of age he has had but one death, and that was from pneumonia. In seven operations in children under two years of age there was but one death, the patient being moribund at the time of the operation.

Bassini's method of operation is preferred. In four cases out of seven the cæcum was found in the sac. Strangulation in infants is more common than is generally appreciated, and not infrequently arises from the bad advice to postpone wearing a truss until the age of one year.

As to treatment, gentle taxis should be tried for one or two minutes; if this fails, applications of hot cloths should be made for from fifteen to twenty minutes, followed by taxis under chloroform, after all preparations for operation have been made. If this is also unsuccessful, immediate operation is to be undertaken. An attempt at radical cure can, in the great majority of cases, be made with safety.

## Reviews.

THE PRINCIPLES AND PRACTICE OF MEDICINE. By William Osler, M.D. Third Edition. New York: D. Appleton & Co., 1898.

There are few books which receive professional confidence and esteem to the extent of that received by Dr. Osler's well known work, for three large editions have been presented to us in a period of about six years. The book appeared at a time when there was a need for a new work on this subject, and possessed a touch of originality which set it apart from its competitors. Each new edition has shown increasing care in editing the pages, and many sentences which were evidently dictated and inelegant have been revised. This particularly is the case in the present edition. In the department of therapeutics erroneous statements have also been corrected, but this part of the volume is still its feeblest part, as it is perhaps the portion to which its distinguished author has devoted least attention. This is all the more unfortunate in that in this portion the text is particularly assertive and dogmatic. While these views may be those of the author, less respect is shown the views of others in this portion than in pathology and symptomatology, and the rather sneering allusions to recognized therapeutics indicate a disregard of the whole object of medical research, namely, the care of the patient. Thus under erysipelas we are told in a very imperfect and impractical way of the treatment to be instituted, and finally it is stated that while ichthyol is much used cold water is "as good an application as any," all of which proves that the author either has not tried the present methods or has studied their results so carelessly as to fail to grasp the results accruing. Dogmatism is wise only when based on observation.

The present edition has evidently been revised thoroughly and we believe entirely reset in type. The first article on typhoid fever shows careful revision, and a very pleasant feature of it is that in the treatment of this disease the author, while indorsing the Brand treatment, recognizes for the first time that it has many limitations and that it can be modified with advantage at certain times and in certain cases. This is certainly the correct therapeutic attitude.

Dr. Osler's discussion of appendicitis is wise and conservative, for while he appreciates the fact that an operation is very often

essential, he recognizes that all cases do not need operation. He refers to the so-called "appendicitis fad" and quotes the case of a physician who suffering from ordinary "bellyache" called in a friend, who at once removed his appendix!

A BLOOD CHART. Designed by J. C. Da Costa, M.D. Philadelphia: The J. B. Lippincott Company, 1898.

To those who do work in clinical medicine of a careful character microscopical and chemical examinations are necessary, and often it is important to preserve records of these examinations in a diagrammatic manner, just as it is useful to have a temperature chart. This chart has been designed for the purpose of preserving blood records. Spaces are provided at its top for the necessary information regarding the case, and in the body of the chart spaces are also made for the date, color index, grammes of hemoglobin, specific gravity of blood, percentage of hemoglobin, and the number of white and red blood cells, while at the bottom of the chart are spaces for the record of the various forms of red and white cells. Such a chart is a difficult one to prepare, and Dr. Da Costa seems to have succeeded very well in filling all the requirements of the case.

A TEXT-BOOK OF PRACTICAL THERAPEUTICS. With Especial Reference to the Application of Remedial Measures to Disease and Their Employment upon a Rational Basis. By Hobart Amory Hare, M.D. With special chapters by Drs. G. E. De Schweinitz, Edward Martin, and Barton C. Hirst. New (7th) Edition, thoroughly revised. Illustrated. Philadelphia: Lea Brothers & Co., 1898.

The following is the preface to the seventh edition:

"The continued favor shown by students and practitioners of medicine toward this book, once again exhausting a large edition in about nine months, has naturally given its author great pleasure, because this favor indicates that it brings to their hands information which proves valuable in actual practise. In the preface to the last edition the author stated that every endeavor had been made by rewriting the text and carefully preparing new articles to keep the book abreast of the times and as useful as before. Equal attention has been given to the present issue, and in addition a number of illustrations designed to elucidate descriptions of technique or therapeutic results have been inserted.

"The opportunity has been embraced to make the text conform not only, as it has done, to the Pharmacopœia of the United

States, but also to the British Pharmacopœia of June, 1898.

"By these constant endeavors to maintain the object for which the book was written, it is hoped that it may remain popular with medical readers."

**PRACTICAL DIAGNOSIS.** The Use of Symptoms in the Diagnosis of Disease. By Hobart Amory Hare, M.D. New (3d) Edition, revised and enlarged. Illustrated in colors.

Philadelphia: Lea Brothers & Co., 1898.

The following is from the preface of this edition:

"The fact that three large editions of this book have been called for in two years indicates that it has found favor with practitioners of medicine. No less pleasant to the author is the fact that an equal popularity has attended it in Great Britain. These facts have served to stimulate him to constant endeavor to maintain its usefulness. The text of this, the third, edition has been carefully revised, much important new matter added, and new illustrations, taken from life by photography, have been introduced to render the text more practically useful. The endeavor has been to make this edition prove a companion volume to the seventh edition of the author's Text-book of Practical Therapeutics, which is published simultaneously. With these additions the author hopes that the volume will continue to deserve the favor with which it has so far been received."

**PERNICIOUS FEVER.** By Dr. Joao Vincente Torres Homem, of Rio Janeiro. Translated by Surgeon George P. Bradley, U. S. N.

Detroit, Mich.: William M. Warren.

This small octavo volume deals with a subject which has recently come to possess extraordinary interest to many physicians in this country by reason of the fact that many soldiers are returning from Cuba and Puerto Rico suffering from forms of malarial fever which heretofore have not been met with by American practitioners. The volume first deals with the symptoms of pernicious fevers, then with the diagnosis of the various forms, which the author discusses under the heading of Algid, Ardent, Comatose, Cerebro-meningeal, Convulsive, Delirious, Neuralgic, Pneumonic and Rheumatic Pernicious Fever. Finally, the volume closes with a discussion of the pathological anatomy and with a chapter upon treatment.

As a brief handbook of this subject, at the cost of twenty-five cents in paper, fifty cents in cloth, the volume is well worth having.

**WOUNDS IN WAR.** The Mechanism of Their Production and Their Treatment. By Surgeon-Colonel W. F. Stevenson.

New York: William Wood & Company, 1898.

This book, founded on the author's lectures in the Army Medical School, is destined to indicate the lines on which the modern treatment of wounds in war should be carried out in special injuries of particular parts of the body, and to point out what methods are calculated to bring about the best results in the preservation of lives and limbs in individual cases.

The first chapter is devoted, in the main, to portable firearms and mechanical projectiles and is one of exceeding interest. As is natural, the author decides that the Lee-Metford is the best military small arm in existence.

The next chapter is devoted to the characteristics of the injuries produced by projectiles. We find here a most instructive discussion of the injuries produced by small bores and the theoretical and true explanations of the explosive effect, together with illustrations. The third chapter is devoted to the primary phenomena and symptoms of gunshot wounds, including of course pain, shock, and hemorrhage.

The general treatment of wounds is next discussed, after which are taken up certain regions, such as joints, long bones, the head, the neck, the spine, the chest, the abdomen, etc. There is a chapter upon the effect of the use of modern small arms in the wars of the future, particularly in its relation to the surgeon's work, and a final one upon the Geneva Convention.

The book is a thoroughly readable one, and its contents should be well known by every military surgeon.

**AN AMERICAN TEXT-BOOK OF GYNECOLOGY, MEDICAL AND SURGICAL, FOR PRACTITIONERS AND STUDENTS.** Edited by J. M. Baldy, M.D. Second Edition, revised.

Philadelphia: W. B. Saunders, 1898.

This second edition of An American Text-book of Gynecology has been called for because of the popularity of the works edited by Dr. Baldy. Its revision has been necessitated by the rapid and progressive advances in gynecology. Many of the most important subjects are considered from an entirely new standpoint, and new chapters have been added, one particularly on technique and after-treatment. The authors who have contributed to this volume are: Henry T. Byford, J. M. Baldy, Edwin B. Cragin, J. H. Etheridge, William Goodell, Howard A.

Kelly, Florian Krug, E. E. Montgomery, William R. Pryor, and George M. Tuttle. They are all teachers in this branch of surgery in leading medical schools and hospitals and are all acknowledged as authorities. Dr. Baldy states that the work embodies, as nearly as possible, the combined opinions of all of the authors, and that his object is to make it thoroughly practical in its teaching, so that it may be a working text-book for physicians and students. In this he has thoroughly succeeded. The book has a wealth of illustrations and will hold its place in the front rank of a branch of surgery traversed by a number of admirable text-books.

A MANUAL OF MODERN SURGERY, GENERAL AND OPERATIVE. By John Chalmers Da Costa, M.D. Philadelphia: W. B. Saunders, 1898.

It is with the assurance of finding a clear, concise, accurate and comprehensive book on modern surgery that the reviewer opens the second edition of this admirable work by Da Costa. It is admitted by the author to occupy a ground between a text-book and a compend and has, he states, been practically rewritten. Among the changes to be noted are the addition of sections on the surgery of the liver and gall-bladder, the spleen, the pancreas, the female breast, wounds inflicted by modern projectiles, electrical injuries, and the use of the Roentgen rays. He has also described all the newer operations which have been proven of distinct value.

This work is worthy of the highest praise. It is destined to be both a text-book for the student and a handbook for the practitioner, and will add to the reputation of its distinguished author.

A MANUAL OF SURGERY FOR STUDENTS AND PRACTITIONERS. By William Rose, M.B., B.S. Lond., F.R.C.S., and Albert Carless, M.S. Lond., F.R.C.S. New York: William Wood & Company, 1898.

In this book of eleven hundred and odd pages the authors have endeavored to present the facts of surgical science in a concise and succinct form so as to satisfy the needs of the student and at the same time the requirements of the general practitioner.

As is customary in all such works, the opening chapters are devoted to inflammation, suppuration, ulceration, gangrene, sepsis, and infection. The text on these subjects represents the teaching of the day.

In dealing with wounds modern surgeons are somewhat surprised to find the method used at King's College Hospital described as practicable and efficient. This method is as

follows: "The *hands* of the surgeon must be rendered pure by washing them thoroughly with soap and water; the nails must be cut, if need be, and cleansed, special attention being directed to the reflection of skin at their base, where septic material is so apt to collect; for this purpose a purified nail-brush may be employed with advantage. The hands are then immersed in carbolic lotion (preferably 1 in 20), which penetrates the skin and acts more efficiently than a sublimate solution." The objections to this method are: (1) that it is inefficient; (2) that a 1:20 carbolic solution so numbs the hands as to render them practically useless; (3) that it will set up in such people an acute dermatitis, rendering it entirely impossible to sterilize the hands, even by efficient methods, after five or six washings in 1:20 carbolic solution. Such teaching tends to lessen confidence in the practical experiences and modern knowledge of the authors.

We find three varieties of shock—active, torpid, and erythritic—certainly not a good classification for the student nor a serviceable one for the practitioner. The paragraph on diagnosis is quite useless.

Throughout the book there is a use of italics and black print not always happy in its effect, which should be to concentrate the reader's attention upon points of cardinal importance. Also there are many pages of fine print, the reason for which does not seem obvious.

In discussing hernia the authors hold that the radical cure is not an essential but only a desirable means of treatment, and describe in full the method of Mitchell Banks.

In due fairness it should be said that the authors have succeeded in presenting the science of surgery in a comparatively limited space. It cannot, however, be claimed that this has not been done as well by others, nor are the teachings of this work more modern.

ATLAS AND EPITOME OF OPERATIVE SURGERY. By Dr. Otto Zuckerkandl. Authorized Translation from the German. Edited by J. Chalmers Da Costa, M.D. With 24 colored plates and 217 illustrations in the text.

Philadelphia: W. B. Saunders, 1898.

This work, which is apparently designed mainly as an aid for the student in his operative work on the cadaver, is characterized by profuse and excellent illustrations. The operations are described concisely, the most modern methods have been included, and the book is designed to be serviceable to the practising surgeon.

ATLAS OF SYPHILIS AND THE VENEREAL DISEASES. Including a Brief Treatise on the Pathology and Treatment. By Prof. Dr. Franz Mracek. Authorized Translation from the German. Edited by L. Bolton Bangs, M.D.

Philadelphia: W. B. Saunders, 1898.

The greater part of this book is taken up by seventy-one plates, nearly all colored, reproduced from water-colors with surprising fidelity to pathological appearances. Attached to each plate is a signature embodying the history of the case, the condition at the time the picture was taken, and the treatment and its results. There follows 117 pages of text, embracing syphilis, venereal ulcer, and gonorrhea. There is thus presented at a moderate cost an atlas the illustrations of which are of unusual merit, and a summary of treatment so arranged as to admit of immediate reference.

A CLINICAL MANUAL OF SKIN DISEASES. By W. A. Hardaway, A.M., M.D. Second edition, revised and enlarged.

Philadelphia and New York: Lea Brothers & Co., 1898.

This second edition of Hardaway's manual, thoroughly revised and containing the most recent therapeutics which are found serviceable, is destined to receive even more favorable attention than that which was accorded the first edition. There is a handier system of classification, and the book is better suited to the needs of the general practitioner. It should be noted that the greater bulk of the volume is devoted to diagnosis and treatment.

There are a number of excellent illustrations and the text is clear and direct. It is unfortunately true of skin diseases that many of them are persistent under the most skilful treatment. By following the directions given in this manual the practitioner may, however, have the satisfaction, even in the more difficult cases, of knowing that he is doing the best for his patient that science has to offer.

Those fond of prescriptions will be gratified by the very large number of excellent ones to be found in this work.

LECTURES ON TUMORS. By John B. Hamilton, M.D., LL.D. Third Edition.

Philadelphia: P. Blakiston, Son & Company, 1898.

In this the third edition of Hamilton's well known brochure is an entire rearrangement of nomenclature and illustrations. The work is intended for students and to serve as a recitation book, and seems well fitted for this purpose.

HANDBOOK FOR THE HOSPITAL CORPS OF THE U. S. ARMY AND STATE MILITARY FORCES. By Charles Smart, Deputy Surgeon-General, U. S. A. Approved by the Surgeon-General of the Army.

New York: William Wood & Company, 1898.

This revised edition of Smart's book, which has been adopted by the Medical Department of the United States Army for the instruction of hospital corps men, is well adapted to its purpose. The first part is devoted to hospitals and hospital duty and will prove useful not only to the hospital corps, but to every medical officer who serves the troops.

The section on elementary anatomy and physiology is well suited to its purpose.

The section devoted to the special needs of the hospital corps has to deal mainly with surgical and medical emergencies.

There is an excellent chapter on Elements of Cookery, which, though brief, is extremely instructive. The book is heartily to be commended.

A GUIDE TO THE CLINICAL EXAMINATION OF THE BLOOD. By Richard C. Cabot, M.D. Freely Illustrated. Third Revised Edition.

New York: William Wood & Company, 1898.

With the extraordinary progress which has been made in the study of the blood as a tissue and of its relations with diseases manifesting themselves elsewhere, it has become necessary that the profession should be provided with a summary of our knowledge concerning hemology, and Dr. Cabot has provided us with a volume which possesses great value. As we have pointed out before, this book is emphatically the work of one who has studied the blood until he has obtained a large personal experience. Indeed, this very advantage almost amounts to a disadvantage in that the text is often such a bare description of fact, or of technique, that it is more difficult to read than if the author had used his pen with a freer hand. The fact, however, that three editions have been called for within a very short time not only proves the value of the book, but also that a need for its existence was felt by the profession. The principal additions to the present volume are an account of Professor Oliver's tintometer and hemoglobinometer, which we are told are the only two instruments of importance, and new matter has been introduced upon the primary anemias, upon leucemia, and upon Müller's blood dust, the newly discovered constituent of normal and abnormal blood. Various blood tests have also been described. In order to save space and in view of the impossibility of publishing a complete list of bibliographical references, this list has been ex-

punged, excepting where very important articles are referred to. This, it seems to us, is a valuable innovation, as it not only saves burdening the book, but tells us what the author considers to be the best literature on a given topic.

DIPHTHERIE UND DIPHTHERITISCHER CROUP. Von Dr. Adolph Baginsky. Mit 68 Abbildungen, davon 19 in Farbendruck.

Wien: Alfred Holder, 1898.

This volume is a part of a series having the curious German title of "A Handbook for Special Pathology and Therapy." It will be seen at once that as it is written by Professor Baginsky it comes from one of the highest authorities upon this very interesting disease, and like most volumes written by leading lights in the German medical world it is a splendid contribution to the literature of this subject. It is exhaustive and gives one practically all the information he can possibly desire concerning diphtheria and closely allied affections, both historically, etiologically, and pathologically. After an exhaustive discussion of the symptomatology of the disease, when it occurs alone or in connection with other maladies, and of the complications that may arise in its course, it discusses the diagnosis, the prognosis, and finally the therapy, of diphtheria. It is needless to say that the author discusses in a very able way the whole subject of serum-therapy. After doing this he proceeds to discuss the subject of treatment of stenosis of the respiratory passages due to the membrane.

The volume from one end to the other is increased in its value by the copious references and foot-notes which the author has supplied, and shows not only a complete knowledge of the literature of the subject, but an intimate personal acquaintance with its clinical aspects. There are so many physicians in America who can read German with ease that we doubt not that many of our readers will benefit themselves by obtaining this volume.

THE JOHNS HOPKINS HOSPITAL REPORTS. Report in Pathology. A Review of the Pathology of Superficial Burns. By C. R. Bardeen, M.D.

The Johns Hopkins Press, September, 1898.

This brochure of 179 pages deals with an exceedingly interesting subject about which much has been written by physicians and surgeons. Dr. Bardeen points out, however, that much of the literature is scattered and still more of it is based rather on hypothesis than upon the actual study of the pathology

of burns. After giving a historical summary of the literature and discussing the various theories as to the cause of death after burns, he goes on to tell us that he believes toxemia plays a very large part in the cause of death, and calls particular attention to the lesions which are found in the lymphatic system after more or less severe burns, these lesions not having received sufficient emphasis from previous writers. The research does not bear directly upon any methods which can be introduced for the purposes of treatment, but is a valuable summary of our knowledge of the subject and of the results reached by the author from the study of a number of cases of severe burns.

A MODERN TEXT-BOOK OF THE DISEASES OF CHILDREN. Edited by Louis Starr, M.D., assisted by Thompson S. Westcott, M.D. Second Edition, revised.

Philadelphia: W. B. Saunders, 1898.

This book is known far and wide throughout the United States as being a valuable contribution to pediatric literature, and has perhaps done more than almost any other volume to advance the study of the diseases of children amongst American practitioners—not that there were no first-rate books written by individuals upon this subject, as for example that of J. Lewis Smith, but because this made an opportunity by which the profession could obtain the views of a number of thoroughly competent men particularly qualified to write the articles assigned to them.

In the present edition a number of the articles have been revised. A section on orthopedics has been introduced, and about fifty new pages have been added to the volume. The volume is one of the best of its series and deserves all the confidence which it has received. It is sold by subscription, the cost being seven dollars in cloth.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science. Edited by Thomas L. Stedman, M.D. In twenty volumes. Volume XV: Infectious Diseases.

Ten authors contribute the six hundred and forty pages which make up this issue, and they are gathered from far distant parts. The articles are by Dr. Frank S. Billings of Grafton, Mass., Boas of Berlin, Finkler of Bern, Gaston of Atlanta, Keirle of Baltimore, Kitasato of Tokyo, Leiceaga of Mexico, Nakagawa of Tokyo, and Ponfick of Breslau.

The first article on Influenza is by Ditmar Finkler, and this important subject is given no less than 250 pages, or about one-third of

the volume. As may be imagined the disease is exhaustively considered from almost every standpoint, and the facts the author desires to enunciate are emphasized by frequent quotations from the histories of patients. The article upon Typhus Fever by Leiceaga is about seventy pages in length, and is followed by a very interesting but exceedingly brief one upon the Plague by Kitasato and Nakagawa.

Billings' article is upon Glanders and Anthrax and is quite exhaustive, while Boas writes upon Foot and Mouth Disease, and Ponfick upon Actinomycosis. Keirle's article deals with Rabies quite exhaustively, and the concluding article of seventy pages upon Pyemia and Septicemia is by the Gastons, senior and junior.

We have previously spoken in terms of praise of this monumental work and have called attention to the fact that the articles and volumes must necessarily vary somewhat in value. We consider this particular volume an exceedingly creditable part of the system.

CLINICAL TEXT-BOOK OF MEDICAL DIAGNOSIS. By Oswald Vierordt. Authorized Translation with Annotations by Francis H. Stuart, A.M., M.D. Fourth American from the Fifth German Edition. Copiously Illustrated.

Philadelphia: W. B. Saunders, 1898.

This is one of the most successful books upon diagnosis which has been published, less than nine years having elapsed since the date of the first edition, and it has been received abroad even a little more enthusiastically than in this country, although the four editions which have followed each other rapidly on this side of the ocean have shown that the American physician is anxious to obtain all the aid that he can in this difficult portion of medical study. To those who are not familiar with the volume we may state that the first portion of it deals with what is known as "Diagnosis," or largely with those symptoms which we actually see, whereas in the greater portion of the book, which is devoted to special diagnosis, are given the details which are necessary for the more minute and satisfactory examination of patients. While the text of the book lacks sequence to some extent, it contains an immense amount of exceedingly useful information. Its illustrations are good in so far as they illustrate the text, although their mechanical production is not of the best. It is a volume which any advanced physician would be glad to have on his shelves. Its price is four dollars in cloth.

## Correspondence.

### LONDON LETTER.

By RAYMOND CRAWFURD, M.A. OXON., M.D., M.R.C.P. LOND.

Medicine will have made a substantial advance in the day when leucocythemia is brought within the range of practical therapeutics. Every physician must be conscious of his inability not only to stay the progress of the disease, but also to mitigate the suffering that follows in its wake. Arsenic is not only useless, but in many cases actively harmful. We turn therefore with more than ordinary interest to Ewart's remarks on the treatment of two cases by inhalations of carbonic acid gas. The gas is generated in a Kipp's apparatus and freed from hydrochloric acid by passing it through a wash-bottle containing twenty-per-cent. solution of carbonate of potash. The amount of gas inhaled can be gauged with sufficient accuracy by watching the amount of bubbling in the wash-bottle. The inhalations are given for seven to ten minutes several times a day, and to guard against any respiratory complication oxygen is administered simultaneously through another tube. Ewart claims to have obtained very great improvement in two cases of leucocythemia by this method. It is necessary to add that the inhalations were combined with galvanism to the spleen for five minutes before and during the whole process. However, we do not seek to discount Ewart's results by reason of this super-added remedy, as in our experience galvanism has always and completely failed to produce any diminution in size of the leucocythemic spleen, and in more than one case has seemed to set up severe and abiding pain. We shall await with interest the results obtained by other physicians with this method.

Surgeon-Captain Foulkes has an ingenious suggestion for facilitating the extraction of the guinea-worm, and preventing its breakage. His method is at first the usual one of rolling the worm round a piece of paper. After a few inches have been extracted in this way, alcohol is injected into the remainder of the worm so as to harden it *in situ*; in about an hour the rest of the worm can be easily extracted. Foulkes found that in some cases the alcohol did not travel to the extreme limit of the worm, and a small portion would then be snapped off and remain in the wound. To prevent this contingency he added a small quantity of fuchsin

to the alcohol, so that the dye marked the distance to which the alcohol had traveled, and in this way all casualties were eliminated. Foulkes also noted that whereas the retention of a portion of the untreated worm usually induced local suppuration, if a portion of the alcoholized worm were left in the tissues it behaved like an aseptic ligature and was absorbed. Another advantage of the use of alcohol is that it leads to shrinking of the worm in the tissue sheath, which by reason of its tightness hinders entire extraction. The method commends itself as much by its simplicity as by its ingenuity.

As a subject for abstract academic discussion the question of the relative digestibility of white and brown bread might seem one of second-rate importance, but Lauder Brunton and Tunnicliffe, out of deference to the solicitude of the sick laity, discuss the subject seriously and usefully in the *St. Bartholomew's Hospital Reports*. Briefly, their conclusions may be summarized as follows: (1) White bread is, weight for weight, more nutritious than brown. Brown bread chemically should be more nutritious than white only in fats and mineral constituents; but in the process of digestion distinctly less of the nutritive materials actually get into the blood in the case of brown than of white bread. (2) In the case of people with irritable intestines, white bread is to be preferred to brown. Cellulose mechanically irritates the intestine; the larger the flakes of cellulose, the greater the irritant action. In irritable intestines it will even provoke diarrhea, and so interfere with the absorption of much nutritive material. (3) In the case of people with sluggish intestines, brown bread is preferable to white, as it tends to maintain regular peristaltic action, and insure regular evacuation of the bowels. (4) In cases where the proportion of mineral ingredients and especially of lime-salts in other articles of food or drink is insufficient, brown bread is preferable to white. It is possible that in the case of operatives living chiefly upon bread and tea, the preference for white bread which obtains in large towns may be responsible in part at least for the early decay of the teeth of those living on such a dietary. (5) An abundant supply of mineral constituents is especially required in pregnant and suckling women and in growing children, in order to supply material for the nutrition of the fetus, the constituents of the milk, and for the growth of the tissues, especially of the bones. In such cases, if mineral salts, espe-

cially those of calcium, are supplied by other foodstuffs, drinks, or medicines, brown bread is preferable to white. (6) If the dietary is insufficient in fat, or if the patient is unable readily to digest fat in other forms, brown bread may possibly be preferable to white.

Martin and Cherry recently communicated to the Royal Society some experiments on the nature of the antagonism between toxins and antitoxins, which are of first-rate importance in these days of antitoxin therapeutics. Their observations directly contradict those of Calmette and his school, who maintain that antitoxins act in some indirect way through the medium of the cells of the body, and confirm the view enunciated by Kanthack, Behring and others that the antagonism is of a directly chemical character such as the neutralization of an acid by an alkali. Calmette's experiments were made with cobra toxin and its antitoxin. The cobra toxin is not attenuated by heating its solutions to 68° C. for ten minutes, while the antitoxin is completely destroyed. Calmette showed that mixtures of toxin and antitoxin were innocuous to rabbits, but that if after ten minutes' contact the mixture was heated to 68° for ten minutes, it at once became lethal. From these experiments Calmette denied the direct chemical character of the reaction between the toxin and antitoxin. On the other hand, Kanthack has shown that the property possessed by cobra toxin of preventing the coagulation of blood in the test-tube is lost if the toxin be mixed with Calmette's antivenomous serum. Martin and Cherry's experiments show that Calmette's inference is quite untrustworthy, because he has made no adequate allowance for the factors of time and temperature in the possible chemical interaction of toxins and antitoxins. Their experiments were made with the diphtheria toxin, and also with one of the constituents of the poison of an Australian snake, which is apparently identical with the cobra toxin, and is more or less decidedly counteracted by Calmette's antivenomous serum. Their first experiments were designed to show by a direct method that the action of antitoxins upon toxins was chemical, not physiological; the basis of the experiment was the known fact that substances of different molecular size, when in combined solution, may be separated by filtration. The filtration was effected through a film of gelatin in the wall of a Pasteur-Chamberland filter under a pressure of fifty atmospheres. A standardized solution of diphtheria toxin was thus

filtered, and the filtrate found to contain the toxin, though diminished in toxicity. Brodie showed in his Arris and Gale Lectures of last year that the antitoxin does not pass through such a filter; consequently the toxin and antitoxin of diphtheria may be readily separated from each other, provided there have been no chemical reaction between the two beforehand. Martin and Cherry allowed the solution of the combined toxin and antitoxin to remain for two hours at 30° C., and then submitted it to filtration. The result was that the filtrate contained no toxin, and was quite harmless on injection. The only obvious conclusion must needs be that the toxin had undergone some change of molecular size, and this can hardly have been caused by anything else than chemical interaction of the toxin and antitoxin.

Martin and Cherry have also repeated Calmette's experiments with the cobra toxin, and have shown that by varying the factors of time and temperature results can be obtained in direct contradiction to those obtained by Calmette. On the whole, therefore, Calmette's experiments rather confirm the view of some direct chemical interaction—the very conclusion they were designed to confute. To this end nearly all the most recent observations converge. In the spring of this year some interesting observations by Stephens and Meyer in Professor Kanthack's laboratory at Cambridge were communicated to the Pathological Society of London. Cobra toxin was shown to exercise a hemolytic action on blood in the test-tube, but after admixture with a given proportion of antivenomous serum, the hemolytic action of the solution was lost. It is difficult to explain this change of toxicity on any other than decidedly chemical grounds.

In this country Dr. O'Connor, of Lowestoft, has taken advantage of the ready passage of antitoxin serum through animal membranes to administer the antidiphtheritic serum to his patients per rectum. He claims to have got strikingly good results by this method, and with a marked absence of complications. Certainly the rectum is a more convenient receptacle for the bulky doses that must be administered than the subcutaneous tissues. An advantage which O'Connor claims for this method of administration is that it renders more manageable the viscid solutions obtained by dissolving the solid sera. The dosage of the antidiphtheritic serum, when administered by rectum, should be guided by the same rules as apply

to its hypodermic use, as absorption by the rectal mucous membrane appears to be both rapid and complete. We trust that Dr. O'Connor's recommendation with regard to antitoxic sera may in the near future be found applicable to the many multiple nauseating drugs of the Pharmacopœia. Dr. O'Connor's praises would be told by the mouths of babes and sucklings.

---

#### PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

In our last letter we spoke of the Congress of Tuberculosis held in Paris from the 27th of July to the 3d of August, and, as we indicated, the principal subjects discussed were the prophylaxis of consumption and its treatment in sanatoria.

So far a few well regulated sanatoria have been constructed in France, but the latter have always been established for rich people or people of means, and hardly anything has been done for the poor. It is, of course, useless to try to stamp out tuberculosis unless all classes of society are treated for it, and so the founding of asylums for tuberculous patients of the poorer classes was naturally discussed at length.

Dr. Legendre, physician of the Paris hospitals, discussed the advisability of erecting large sanatoria. He insisted on the following points: It would be better to have small sanatoria situated near the large cities, as the expense of traveling, both for the patients and their families, should be taken into account. The question of climate is also to be considered, and various sanatoria should furnish different sorts of climate according to the season of the year. Lastly, according to his mind, the maximum number of beds should be about twenty, four to twenty being about the right number.

Dr. P. Koninojy described the sanatoria founded at Grabowsee and Ruppertshain. These asylums are to serve as models for the thirty similar establishments which are to be erected in various parts of Germany by the Society of the Red Cross. The sanatorium of Grabowsee is situated in the middle of a forest, which surrounds the lake bearing the same name, and is about three-quarters of an hour's drive from the railway to Berlin. There are three large buildings and thirteen smaller ones, each of which is divided into three compartments. There are four beds in the two end compartments, and the mid-

dle one is used as a sort of sitting-room. All the windows in the larger buildings open to the south; on the north side there is a plain wall. There is a window left open in each room at all times of the day and night. Each patient is supposed to clean out his spittoon and wash it with corrosive sublimate. The treatment consists in hydrotherapy, frictions, and rest in the open air. Patients are weighed and examined every two weeks. Their expectoration is examined every three weeks. The price for paying patients is three marks, the cost for each bed being 2 marks 85 pfennigs.

Dr. Schrötter, of Vienna, had a few words to say on the treatment of consumption. He described the spittoons used in Austria, which are made of compressed paper, impregnated with paraffin. They are quite watertight, burn very readily, and cost about half a cent apiece.

Dr. Landouzy presented a spittoon made by Collin, the great instrument-maker in Paris, on plans furnished by R. Simon, of Paris. This pocket spittoon is made of black glass and metal, about the size of a large whistle, and its appearance does not produce a disagreeable impression. It is furnished with a cover that fastens down hermetically, but has no spring, and is supplied instead with a piece of rubber, which serves to make the cover spring back. There is an opening below closed by a cap that is screwed on, and this opening serves to empty the spittoon when it is full. Another point in favor of this receiver is that the orifice is obliquely inclined so as to allow the patient to expectorate readily.

Dr. Churquet, of Cannes, spoke after Dr. Landouzy, and said that one should insist on the cover being so arranged that, when the latter is opened, no part of the expectoration should be thrown off.

What is of as much importance as the spittoon is the way in which it is sterilized, and the following are the means that obtain in France and elsewhere: One may use the preparation recommended by Dr. Miquel, which is a 2:1000 solution of corrosive sublimate with 20 grammes of chloride of sodium, or a 5:100 solution of carbolic acid, or a 5:100 solution of formaldehyde. After all, the best process is that used at the Boucicaut Hospital. The spittoon containing the expectoration is sterilized under pressure and then cleaned out and washed. In the sanatoria of Falkenstein and Hohenhormef, the expectoration is thrown into the water-closet pit; the spittoon is then sterilized by being

put into boiling water. At Ruppertsheim and Alland the expectoration is absorbed by some peat and the latter burnt. As a general rule the expectoration should not be thrown into the sewers until it has been sterilized.

All these precautions, of course, cost a good deal of trouble, but in some places they are carried out with the greatest regularity. At Leysin, for instance, the patient puts his spittoon outside his door at night on going to bed; he gets it back the next day in perfect condition. For the night and in his room he has a special spittoon.

Dr. Landouzy spoke again at the end of the sitting on the necessity of providing public spittoons in all places such as stations, halls, etc. He trusted that at the 1900 exhibition special attention would be paid to this important subject, and that just as various means of warding against fire are established, a like effort would be made by the committee for the exhibition to inculcate into the masses some idea of the importance of prophylaxis by means of charts, papers, diagrams, and other statistical methods.

Dr. Bouchard, professor at the Faculty of Medicine, and Dr. Claude, his house physician, called the attention of the members of the congress to the use of Roentgen rays to diagnose tuberculosis, and they recommended the apparatus of Guilleminot, in which the radioscope is fixed on the chest of the patient by means of a belt in such a way that the radioscopic effect is only produced during inspiration.

By using this means of diagnosis, Bouchard, Rendu and Maragliano have been able to discover tuberculosis in patients who have none of the ordinary symptoms. These authors indicated the following means of recognizing consumption: One should always examine the natural condition of the lung in a healthy subject. When there are lesions, instead of there being uniform transparency, there exist small granulations, sometimes a sort of veil or foggy appearance at the summit of the affected lung. Another important modification is the greater or less clearness of the clavicle, which if rather indistinct indicates a modification in the permeability of the lung. Later on the obscurity increases, and it is absolutely impossible to perceive the outline of this bone. The diaphragm is also affected. It does not ascend as far as in a normal condition. Such are the two principal symptoms at the beginning of consumption. When the case is more advanced, and the lung destroyed in part, it may prove of some

interest to recognize to what extent the lung may be affected. In such cases the Roentgen rays indicate a cavity by a sort of light spot surrounded by a black circle. One may follow the repletion or depletion of the cavity. Various membranes, adhesions, diaphragmatic pleurisy, pleural symphysis, can be discovered, thanks to the retraction of the lung. Interlobular pleurisy may be distinguished from an abscess of the lung, as the latter is characterized by a well defined opacity surrounded by a clear zone. In emphysema the symptoms are very apparent; there is a luminous tendency which is quite perceptible. The ribs and the vertebræ are less sharply defined, perhaps on account of their chemical composition being slightly modified, according to some American authors, there being more salts of magnesium than formerly. An irregular appearance of the lung tissue is readily perceived, due perhaps to bronchial sclerosis. The diaphragm is drawn down. The vertical dimension of the thorax is increased. In hydatid cysts there is often a peculiar appearance due to an opaque zone surrounded by a spherical membrane. In short, the  $x$ -rays are an excellent means of controlling the diagnosis and revealing consumption in its initiatory stages.

---

#### BERLIN LETTER.

BY JAMES J. WALSH, PH.D., M.D.

---

During the university vacations I have been in Munich. The University at Munich was of course closed, so I found subjects for study in the methods of two of the best known and most successful "irregular" practitioners in Europe—Hessing at Göggingen, in Bavaria, the instrument maker, and Pastor Kneipp, "the water-curer" at Wörishofen. Pastor Kneipp has been dead for over a year now, but Kneipp institutes exist everywhere, and his disciples have increased since his death.

Here was an example of a simple country clergyman who, without any scientific knowledge of diseases or their cure, has won for himself an immense following not alone among the uncultured, but among some of the best educated in Europe. Wealth flowed into his church treasury unsought and unasked. The little town of Wörishofen doubled, then tripled, in size in order to accommodate the visitors who came to take the cure under his direction, and the number of such visitors each year ran up into the tens of thousands.

Thousands who had consulted regular physicians in Europe without relief for their ailments went to Wörishofen and came away cured. The secret of his success was cold water and unbounded confidence in his own ability by means of it to cure all the ills that flesh is heir to. One very patent consequence of his success has been a revival of hydrotherapy in professional hands. Everywhere in Europe this is true, but especially in Germany. In the new Charité in Berlin, for which some \$4,000,000 are to be spent in the next five years, a special feature is to be a hydrotherapeutic institute. Most of the German universities now devote special attention to hydrotherapy. It is true in a way that universities have been forced into giving attention to the subject by popular sentiment. In most of the legislatures of the German States, laws have at least been proposed establishing special institutes for hydrotherapy or proposing to institute special professorships in the subject.

Much that Pastor Kneipp has done is founded on an exaggerated idea of the curative effect of cold water; all of it is tinged by a disregard for the permanency of organic lesions, as sublime as anything that tinged medical practise before Rokitansky and the Vienna school had done their autopsies. Pastor Kneipp scarcely pretended to know anything of pathology in the scientific sense of the word. For him the old humoral pathology that lends itself so beautifully to theorizing on alterative and derivative effects of remedies was all-sufficient. No affection was hopeless for him, and only death closed the scene of therapeutic efforts, whose aim was not merely alleviation but cure. His success at times even in cases where the best medical skill had been unavailing was very striking. In the milder affections where some slight functional trouble, exaggerated and inveterated by inherited or acquired neurotic conditions, makes them almost the despair of the ordinary practitioner, the suggestive effect of his absolute assurance of cure, his dietary regulations and hydrotherapy really worked wonders. His career was a striking rebuke for nihilistic therapeutists, and it has been one element in the reaction to physical therapeutic methods that is now in progress all over Germany.

Another irregular whose success has served to illustrate the fact that medical practise is under present circumstances much more an art than a science is, as I have said, Hessing, the instrument maker. He has just been

decorated by the Grand Duke of Luxemburg for the construction of an apparatus for him that enables him to walk, though he seemed practically condemned to bedriddenness for the rest of his life, from the failure to unite of an intracapsular fracture at the hip. Within the year the universities of Bavaria have had to exert their influence to keep the Bavarian Legislature from conferring upon him the right to teach orthopedics as a special branch, with the privilege of giving his students the right to practise it.

It is not only outside the profession that Hessing's merits are acknowledged. I have within the last few months heard two German university professors of surgery commend his work. One of them, the author of a very well known text-book of surgery, that has gone through some six editions, said that he always felt best satisfied, in cases where orthopedic appliances were needed, when he could commend his patients to Hessing. For large tabetic effusion into joints, for instance, he found it after repeated trial much more advisable to have an apparatus carefully constructed by this master hand than to puncture the joint and keep the patient in bed. But Hessing has learned his own value, and does not construct an apparatus now without due compensation, and besides, patients must go to his institute at Göggingen in Bavaria, where for weeks their cases are carefully studied, and then apparatus, after the preparation of models and repeated trials, specially constructed for them.

For this is the secret of Hessing's success—his special study of the application of mechanical principles to each individual case. He is only a cabinetmaker, who first constructed prothetic and orthopedic apparatus for friends and neighbors in his little Bavarian village home, but whose reputation finally brought patients from all over Europe to him. There is no mystery in Hessing's work. It is merely the application of the finest principles of mechanical art to the difficult problems of orthopedics, each case being made the subject of special study. He has taught instrument makers but little that was not in use before, though that little is important. He it was who substituted for leather bands in the application of rigid apparatus to the leg, the use of molded, perforated splints accurately adapted to the parts. He thus secures a large surface of contact between flesh and apparatus and lessens friction, pressure, and discomfort. Some of his methods of applying apparatus

to joints involve the use of new principles. At the hip he has known how to avail himself of the large surfaces furnished by the iliac bones as high up as the iliac crests, to apply apparatus so difficult of adaptation here that fit well, are firmly held in place, and yet do not cause pressure and friction.

So much for the "art of healing" as practised by two of the irregulars. As they have carried me into the subject of physical therapeutic methods I shall continue in the same strain. In mechano-therapy Dr. Zander's (of Sweden) apparatus are being used everywhere in Germany. At first these ingenious apparatus, by which the limbs and trunks are made to execute a series of definite movements for the accomplishment of certain purposes, especially the overcoming of ankylosis and pseudo-ankylosis in joints, were to be found only at the watering-places, at Wiesbaden, Carlsbad, and Baden-Baden. Now all the large cities have them, and most of the hospitals have at least a certain number of the apparatus. The hospital at Moabit, for instance, one of Berlin's large city hospitals, is thoroughly equipped with apparatus for the movement therapy of stiff joints. The ingenious construction of these contrivances on thoroughly practical mechanical principles, and the application of the most varied range of movements by special construction, have given excellent results to this method of treatment, and it is now one of the most effective therapeutic aids the surgeon has. For the physician they constitute a most valuable curative measure in such conditions as the stiffness from chronic rheumatism and atrophies from disuse.

Great hopes were founded a year ago on the possible applications of the Roentgen rays to therapeutics. These have been disappointed, though there has been no lack of ardent workers in the field. While at Marburg some months ago I found that Professor Behring had a magnificent set of apparatus for work with the Roentgen rays. He was very frank, however, in the expression of his opinion that as far as regards bacterial diseases he did not think that the  $x$ -rays would ever be found of therapeutic value. Just as in the use of antiseptics, the strength of the reagent required to kill the bacteria would also kill the tissues in which they were situated, so that colonies of microbes situated below the surface were safe from attack by the new rays.

Dr. Rieder, of Munich, announced a paper for the German Medical Congress at Wies-

baden in April, in which he proposed to demonstrate in plate cultures how much exposure of the plates to the action of the  $x$ -rays inhibited bacterial growth in the exposed parts, though growth continued normally in other parts. He was prevented for some reason from presenting his paper at the Congress, so that there are only his journal articles to refer to. Just before the end of the semester he was made Extraordinary Professor at the University of Munich, so that a certain stamp of university approval is put on his work. Besides the bacterial inhibition in cultures he has seen the  $x$ -rays do good in the parasitic skin diseases, notably those originating from fungi, and in chronic skin disease, as psoriasis and lupus.

Others claim to have had good effects from it in lupus, too, but Professor Lesser, the professor of dermatology at the University of Berlin, in discussing the subject not long ago, said that not much was to be hoped for from it. The reaction to the  $x$ -rays does not occur in all cases, but is an idiosyncrasy of the individual, not always existent even in the same person nor to the same degree. This idiosyncrasy cannot be surely predicated of any given patient. It is extremely difficult, then, to determine how long an exposure will be required to produce a given effect, or whether an effect will be produced at all. For lupus what is attracting most attention just now is Professor Finzen's (of Norway) method with certain actinic light rays. A good deal of encouraging experiment has been done in this line.

---

*THE TRIENNIAL INTERNATIONAL CONGRESS OF PHYSIOLOGISTS AT CAMBRIDGE IN 1898.*

---

BY HORATIO C. WOOD, JR., M.D.,  
Philadelphia.

---

The Fourth International Congress of Physiologists, which met in Cambridge August 23 and continued its sessions for the following three days, was in every way a great success. There was a very large number of papers presented—in fact more than there was time for the Congress to hear—and most of them were of a very high grade, while some were of extraordinary interest, not only for the physiologist but also for the clinician; indeed, several of the latter found it worth their while to attend the Congress as regularly inscribed members. Among these might be mentioned the famous surgeon Professor

Kocher, Professor Sahli of Berne, who is rapidly taking a place among the foremost diagnosticians of Europe, Professor Lauder Brunton of London, and many others of nearly equal repute. Most of the time at the disposal of the meeting was employed in seeing demonstrations and hearing papers. The Congress, however, found time to attend the ceremony of conferring the honorary degree of Doctor of Sciences on several of its members by the University of Cambridge. One of those to receive this great honor was Professor Bowditch, of Harvard University.

The Congress was opened on the 23d of August at ten o'clock by its President, Professor Foster. After alluding to the difficulties under which English physiologists labored on account of the laws regulating vivisection, and requesting the foreign members to have respect for those laws, Professor Foster declared the Congress opened and called on Professor Marey to read his paper. Professor Marey, after showing the necessity of a unification of measurements and methods employed by physiologists, moved the appointment of an international committee for the regulation of the same. Dr. Demoor, of Brussels, followed with a very interesting and important paper on "The Histological Changes Produced in the Cerebral Neurons by Excitation." Dr. Demoor showed lantern slides of histological preparations (by the method of Golgi), illustrating the ganglionic cells of the cerebral cortex. In an animal killed suddenly (by decapitation) while in a normal state the cortical neuron is characterized by the presence of numerous processes, which are furnished with appendices projecting at right angles. After morphine poisoning these appendices, and to a large extent also the processes themselves, disappear. This moniliform state, however, is not peculiar to morphine narcosis, but occurs equally as a result of anesthetization by ether or chloroform. A similar condition of affairs is found after psychical excitation: thus a guinea-pig which was chased around the laboratory until thoroughly frightened presented the moniliform appearance of the neuron well marked. The author regards this simplification of the neuron processes as a sort of contraction of the nervous protoplasm of the cerebral cells due to an excitation of the same.

Dr. Asher, of Berne, read a paper of considerable clinical interest on "The Theory of Lymph Formation." He said the lymph could no longer be regarded as the merely mechanically exuded blood-plasma, nor did

Heidenhain's theory, which looks on it as a secretion of the walls of capillary blood-vessels, seem to him tenable. He himself believes the lymph to be the carrier of poisonous products of the body metabolism, which are transformed by the lymph glands into substances without toxic properties. In support of this theory he has shown, firstly, that the lymph has a distinctly poisonous action if injected into the circulation; secondly, that those substances which increase tissue work, bringing about a larger destruction of bodily proteids, as, for example, drugs increasing the flow of bile, also cause an increase in the rate of flow of lymph from the liver. Salt solution he claims acts as a lymphagogue, not by virtue of any physical property, but because it increases the work of the liver. In the third place Dr. Asher has found that the lymphatic glands undergo a demonstrable histological change, the result of their activity. If one stimulates, through the chorda tympani nerve, the salivary gland of one side, the increased flow of saliva—in other words, the increased metabolism—is accompanied by an increase in the rate of flow in the corresponding lymph channels. As a result of this he has been able to find changes in the submaxillary lymph-glands of the same side, visible both to the naked eye and to the microscope.

In connection with Dr. Asher's paper might be mentioned that of Dr. Biedl, of Vienna, which, although read at another time, had a bearing on the subject. The paper was entitled "A New Form of Experimental Diabetes." Dr. Biedl has found that ligating or cutting the thoracic lymph-duct in dogs causes the appearance of sugar in the urine. He regards this fact of importance, because the glycosuria was not a merely transient one and was therefore a true clinical diabetes. He admitted, however, that in the course of a month or two the sugar disappeared from the urine owing to the formation, as he found by post-mortem examination, of collateral lymph-ducts. The intravenous injection of lymph will set aside the symptoms temporarily. Contrary to the statements of Gaglio, he has found that ligation of the thoracic duct in cases of pancreatic diabetes only increases the percentage of sugar in the urine.

"The Demonstration of the Union of Nerve-fibers with the Cells of the Sympathetic Cervical Ganglion," by Dr. Langley, of Cambridge, proved to be one of the sensations of the Congress. Two months previously the sympathetic nerve of a cat had been

divided just above the cervical ganglion, and a large piece removed to prevent reunion. The pneumogastric was divided in the same way and its central end joined to the peripheral end of the sympathetic. Dr. Langley reasoned if these nerves had grown together, then stimulation of the vagus ought to give the same symptoms that stimulation of the sympathetic would under ordinary conditions. This he found to be the case; if the electrodes were applied to the vagus above its seat of junction electrical stimulation caused separation of the eyelids, dilatation of the pupil, contraction of the vessels of the ear, and the other well known symptoms of sympathetic stimulation. From this experiment Dr. Langley concluded that all the spinal nerves are essentially the same, and, for example, a vaso-dilator can be converted into a vaso-constrictor, and *vice versa*.

Drs. Mott and Halliburton presented a paper on "The Influence of Choline and Allied Substances on the Blood-pressure." The chief interest of their paper lay in the fact that the authors have shown that the cerebral fluid in cases of brain atrophy contains choline, which substance they believe to be the cause of the circulatory disturbance which so often occurs in the course of cerebral degeneration. They have found that the cerebro-spinal fluid from normal individuals when injected into the circulation in moderate doses has no effect; that, on the contrary, from cases of brain disease has a very marked effect, which is a distinct although temporary fall of pressure. The authors achieved precisely the same result from the injection of choline. They have also demonstrated the latter substance chemically in these pathological fluids. As they have found the blood of these patients to be toxic and in the same direction, it is a perfectly plausible supposition that the choline liberated by the breaking down of the nervous tissue of the brain is absorbed into the circulation, causing the peculiar vaso-motor symptoms associated with these troubles.

Dr. Atwater, of Middletown, Conn., had a paper on "Alcohol as a Foodstuff." His experiments, four in number, were performed in the following manner: A man whose body had previously been brought into a state of metabolic equilibrium was placed in a large calorimeter of especial construction; he was fed on diet just sufficient to provide for the necessities of his body, the excreta and air being chemically examined, and the energy given off as heat measured in calories. In

the second series of experiments a small portion of the carbohydrates of his diet was substituted by an amount of alcohol representing the same quantity of potential energy. The author found that the alcohol so ingested was practically entirely oxidized, that the carbohydrate equilibrium was unaltered, but that the alcohol seemed to exercise a slight protective influence over the nitrogenous destruction. These results remained true both for the resting and the working man. The author concluded that alcohol in small quantities was completely oxidized in the body, and that the organism was able to use the carbohydrate presented in this form for the purposes of nutrition—in short, that alcohol was a true foodstuff.

An interesting discussion followed this paper, Professor Meyer, of Marburg, objecting that although the facts of Dr. Atwater were true, nevertheless alcohol was not a true foodstuff, because this extra carbohydrate was not shown to be necessary or useful to the body. To this Professor Bowditch replied that the same was true of bread: we could subsist very well without bread if we were furnished sufficient carbohydrate in another equally assimilable form. Dr. Atwater added that this much was certain: with a diet otherwise insufficient for the work performed, the alcohol prevented the loss of bodily weight—the organism was not driven to feed on itself for a source of the expended energy.

Besides the papers of which abstracts have just been given, there were read such a mass that their mere titles would fill a page. They were, however, mostly of more interest to the physiologist than to the practitioner.

On Friday, August 26, at the general meeting, after attending to some routine business and adopting resolutions of thanks to the various officers whose efforts had made the Congress the success it was, it was decided to hold the next meeting in Turin, Italy, in September, 1901.

President Foster then declared the Fourth International Congress of Physiologists closed.

---

*THE SANITARY CONDITION OBTAINING  
TO THE ENCAMPMENTS AT TAMPA,  
FERNANDINA, AND  
HUNTSVILLE.*

---

BY EDWARD MARTIN, M.D.,  
Major and Brigade Surgeon, U. S. V.

---

At Tampa the troops which had been hurried from the North were encamped, in

the main, on the most favorable ground of that region. This, at best, represented a sandy soil overgrown with the thick palmetto roots, scantily shaded with pine, and with water from four to six feet from the surface. In many camps, notably those placed near the river or bay, water was found within one or two feet of the surface, even before the rains began. In the majority of the camps, after a few days of rain, the water in the sinks lay even with the surface, and during the downpour the fecal and waste matter of the camp, which had been previously buried, was washed up and more or less widely spread over the ground. The region occupied by the troops at Port Tampa was finally converted into a large foul marsh, the shallow, fresh-water ponds of which bred millions of mosquitoes, while the diffusion of excrementitious matter encouraged the multiplication of flies to such an extent that every article of food exposed for a moment became black with them. The rains usually came in the afternoon, working from the east against a brisk westerly wind. They lasted from a few minutes to several hours—sometimes one or two days—and to the Northern men were astonishingly violent, an enormous amount of water falling in a short time.

The water supplied to the troops was piped to their camps. It was of surface origin, was strongly chalybeate, and was that used by the citizens of Tampa and Port Tampa. There had been very little typhoid in these places, and that which occurred was attributed by the local doctors to persistence in the use of water from polluted wells. There were many wells and springs from which water much better to the sight and taste than that piped to the troops could be had. There were a large number of fruit and soft drink booths; the saloons were multiple and accessible, and some of the regiments had their own canteens, selling from them to their own monetary profit—mainly beer. The nights were always cool, and through the day, except in the early morning, there was a pleasant breeze stirring, so that out of the sun the hot days were bearable.

Orders were issued to the effect that troops should boil all the water they used for drinking purposes, but since the vessels required for the observance of the orders were not issued, it was obeyed only exceptionally. A company of a hundred men will drink in a hot climate at least thirty gallons a day. They will not drink hot or lukewarm water.

They object on general principles to the flatness of boiled water. They must have thoroughly drilled and disciplined into them the danger incident to drinking water from any and every source. To make the working of an order to drink only boiled water practicable, each company would require a large boiler and two clean barrels. In my tour of the various camps I found very few in which the preparation of the water was consistently followed out in all the companies.

As might have been expected, following the first outbreak of diarrhea and dysentery, occurring a few days after the troops reached Tampa, there developed an epidemic of typhoid fever wide-spread and severe, but singularly enough sparing in the main the camps of the Third Brigade, which were placed on probably the lowest and most water-soaked ground to be found about Tampa. It is worthy of note, however, that in these camps much greater care was practised in regard to the sterilizing of the water than in most of the others. The typhoid which developed was somewhat atypical—diarrhea, nosebleed, cough and agonizing headache were common; tympany and marked splenic enlargement were often noted; high temperature, intense backache and albuminuria were characteristic of the more severe cases; the pulse was often slow, sometimes extraordinarily so.

Situated as we were, at a port into which it was extremely probable yellow fever would be brought, and keeping constantly alert for the first sign of the disease, which once started among our debilitated soldiers would have been attended by a heavy mortality, it readily can be seen that these cases of typhoid, sometimes sudden in onset, attended by high fever ( $105^{\circ}$ ), slow pulse (40 to 80), great epigastric tenderness, pain in the back, and albuminuria, presented at times a question for differential diagnosis exceedingly difficult to solve, even for the experts in the disease, who differed, however, in but one case which was positively declared by one of them to be yellow fever. An autopsy showed beyond question that the patient was suffering from typhoid.

The fatal cases, and there were many, often perished from suppression of urine, an acute nephritis commonly complicating the fever. Some passed through the fever without taking to bed, and died quite suddenly of heart failure. In a few cases death was due to perforation.

The importance of keeping patients suf-

fering from typhoid quiet was well shown by the appalling mortality incident to the attempt to remove by train to the Northern hospitals those most seriously ill. The Government hospital trains were, however, simply ordinary Pullman sleepers, and the patients were in some cases allowed to walk to the end of the car when need required.

Frank malaria, characterized by regularly recurring chill, fever, and sweat, was rare. There was, however, a very common affection characterized by sudden onset, usually while the soldier was in the sun, rigors, sharp headache, high temperature ( $103^{\circ}$  to  $105^{\circ}$ ), backache, loss of appetite, lasting two to five days with morning remission, subsiding rather suddenly and apparently quite independent of treatment, though quinine in moderate doses seemed sometimes serviceable. In this affection, as in typhoid fever and the chronic camp diarrhea, medicine was of distinctly minor importance; diet and skilled nursing, neither always obtainable, being much more potent factors in the accomplishment of cure.

After weeks of urgent representation on the part of the medical department, and after more than twenty-five per cent. of the pick of the Tampa troops had become disabled by the diseases incident to their environment, the men, or at least a great part of them, were moved to Fernandina, an island on the east coast of Florida surrounded by many miles of tide swamp and infested with mosquitoes. The camp was pitched on a series of hills, evidently old sand dunes; the drainage was good; pits could be dug to any practicable depth without striking water—the drinking-water came from a depth of over 700 feet, and was strongly impregnated with sulphur and iron, but since its universal use by the townspeople typhoid fever had disappeared from their midst.

Before the movement it was stated that malarial troubles were not likely to be benefited, and that the troops should be taken North, or at least out of the malarial belt. The Fernandina camp was, however, a great improvement on that of Tampa; there were very few flies, the ground was devoid of odor and dried quickly after rain, the sea-breeze blew nearly all day, and the water which was piped to the camp was wholesome. There were, however, a number of surface wells and springs. With one or two hundred men wandering about the country in the early stage of typhoid, it is readily seen how quickly these water-supplies would become

contaminated; that they did so and that they spread the disease is shown by the fact that more than three weeks after the troops arrived in Fernandina new cases of typhoid were developing with alarming frequency. Moreover, as predicted, the malarial affections became rapidly more pronounced.

It was, perhaps, because of the progressive deterioration in the condition of the troops that late in August the movement to Huntsville was instituted. The valley in which this town is situated is wide and fertile, the mountain air is fresh and invigorating, the surrounding country one of great beauty, and providing a continuance in the auto-inoculation process is guarded against by keeping the soldier from drinking the water in wells and springs, and by filtering or boiling all the water that they drink, two or three weeks in this camp would go far toward repairing the debilitation incident to a two months' stay in Florida.

#### *APOCYNUM CANNABINUM.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: It seems that Dr. Dabney, of New Orleans, and his critics are having some trouble in regard to whom is entitled the priority in the introduction of *Apocynum cannabinum* in the treatment of dropsical affections. One who was considered inspired tells us that "there is nothing new under the sun," and this controversy happily illustrates the truth of that adage.

Without claiming any proprietary interest either in the name or use of *Apocynum cannabinum*, I will state that, at the suggestion of a brother practitioner, I began the use of it in the year 1881, seventeen years ago, and have been using it pretty regularly ever since; but I never imagined I was using anything but an old, valuable, but unfortunately almost obsolete, remedy. In Geo. B. Wood's Practice of Medicine, edition of 1858, page 381, it is mentioned as a remedy for dropsy. In Pareira's Materia Medica, edition 1866, page 552, we find the following in regard to it: "*Apocynum cannabinum* is powerfully emetic and cathartic, sometimes diuretic, and, like other emetic substances, promotes diaphoresis and expectoration. It produces much nausea, diminishes the frequency of the pulse, and appears to induce drowsiness independently of the exhaustion consequent upon the vomiting. *The disease in which it has been found most useful is dropsy.* In ascites it sometimes causes the

removal of the fluid through its hydragogue cathartic action."

Now Dr. Wood's testimony was given forty years ago, and Dr. Pareira's thirty years ago. From this we can see that it certainly does not belong to the class of new remedies, and no doubt many a poor water-logged sufferer was dosed with this nauseous potion before the present generation of medicos were wearing swaddling clothes.

My individual experience with *Apocynum* has been considerable, and on the whole very satisfactory. Many times have I administered it to patients who had albuminuria, dropsy, dyspnea, and all the clinical features of what we in general terms call Bright's disease, and I have many times seen all these symptoms change and a complete and permanent recovery follow. Of course I am not to be understood as claiming it to be a specific for chronic nephritis in all its forms. Many times it has failed, but it has frequently succeeded when the clinical diagnosis of chronic Bright's disease was justified before using the remedy.

I cannot recommend *Apocynum* in ascites as a substitute for tapping as confidently as does Dr. Dabney. Only last year I gave it continuously to an ascitic patient whose dropsy was produced by a cirrhotic liver, but with no good result. His dropsy continued in spite of the remedy being pushed to the point of tolerance, and he had to be tapped every twenty days until his death.

It is an old and certainly a very valuable remedy, and these gentlemen have done a valuable service in bringing it prominently before the profession, even though neither can justly claim priority in its discovery and use.

J. W. MEEK, M.D.

CAMDEN, ARKANSAS.

\* \* \*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: I have enjoyed your various communications upon *Apocynum*—enjoyed them, because it is amusing to see people making "discoveries" of what hundreds of people have long known. I have used *Apocynum* since 1877 in the treatment of general dropsy, and many times the effects have been exceedingly beneficial.

The two species of *Apocynum* of our country—*A. cannabinum* and *A. androsæmifolium*—differ considerably in therapeutical action. The *A. androsæmifolium* is a cathartic and emetic, and also acts upon the gall-ducts to aid the expulsion of bile. In very small doses it is a tonic to the hepatic function; in larger

doses it is a strong cathartic. The *Apocynum cannabinum* has a different action, seeming to be a tonic upon the absorbent system, as well as a stimulant to the heart's action. It is in this direction that it acts upon dropsy. In order to get the nicer effects upon general dropsy it should be given in doses too small to physic, and when there appears a tendency to loose bowels the medicine should be withdrawn for a few days, but the bowels must not be checked by opiates.

There is another point of view in this matter. The old, nasty fluid extracts of the general druggist cannot be depended upon to produce a nice action of the drug. Those who use them must give doses that poison their patients, and thus defeat their very intentions. I use a good mother tincture of the *Apocynum cannabinum*; for an adult my dose is about one drop of that tincture every three hours while awake. Should the heart show marked irregularity, with intermittent pulse, I add one-fourth drop tincture of the recent juice of digitalis. If there is marked weakness without febrile reaction, equally minute doses of Fowler's solution and nuxvomica, say half drop of each, are given four times a day as a tonic. In case the legs are greatly swollen I generally add to the Apocynum some trituated chloride of potash, as follows:

- ℞ Apocyni cannabini (saturated tincture of recent root), 3 j;  
Trit. kali chloridi (6th trituration), 3 j;  
Aquæ destillat., 3 iv.

M. Sig.: f 3 j every three hours.

In some cases it is even well to give a saline cathartic to begin with.

With this treatment, which may be kept up for months, if the diet is regulated, I have relieved a good many aged people with diseased hearts, albuminous urine, and dropsical legs. Three years ago I took an old lady of seventy-four, who had not been able to lie down for two weeks, and relieved her completely. She is now alive. The heart disease is there, but this regimen, used once in a while as needed, keeps her comfortable.

Six years ago I saw in consultation a man who was completely filled up with water. He was obliged to sit up in a chair with a frame to support him. All his limbs except the left arm were useless. He was expectorating about two quarts of frothy spittle every twenty-four hours, and all the use he had of himself was to put the cup to his lips for the spittle. This man was so full of water that his heart sounds were not audible. Under

the above regimen and medication the water rapidly left him, and he became able to move about, to sleep in bed, and was comparatively comfortable for three years. He finally died.

I have used, as before stated, both apocynums for over twenty-two years, and feel absolutely confident the *Apocynum cannabinum* acts directly upon the absorbent system to restore its tone and to enable the cells to pass off the accumulated water. I must repeat that no fluid extract will do this, and again that no man who poisons his patients with gross doses of drugs can expect to obtain those finer and beneficial actions which follow a scientific use of medicines.

FREDERICK H. WILLIAMS.

13 PROSPECT ST., BRISTOL, CONN.

\* \*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: I have just read the letter of Dr. Henry M. Cowen anent the claim of Dr. Dabney to the discovery of Apocynum and the use of that drug, running back to a date of "nearly twenty years ago." I wish to add my testimony to that of Dr. Cowen. In 1862-1864 I was practising medicine in the State of Indiana, during which time a friend gave me an old copy of Prof. John King's American Eclectic Dispensary or Dispensatory, *which was then an old book*—probably having been published more than twenty years. I distinctly remember Dr. King's language, as quoted by Cowen. I do not doubt that King's work was published at a date as far back as 1855. I am and have been a reader of eclectic medical literature, and well know that they have for years insisted upon the virtues of Apocynum in the treatment of "dropsies."

With Dr. Cowen, I personally am *a regular*, but believe in giving "honor to whom honor is due."

In closing, I will say that I read no journal that fills the place of the THERAPEUTIC GAZETTE. Recently I have been giving some attention to alkaloidal medication, and read Abbott's Alkaloidal Clinic with great care and pleasure; but *the GAZETTE has its place*—a place occupied by no other publication, a place which, in my judgment, *can be occupied* by no other publication, a place which has been reached and is held by *real merit*. I shall read the GAZETTE as long as I can pay the subscription price. Long live the THERAPEUTIC GAZETTE! I am too old to flatter. I shall try to secure some new readers for the GAZETTE for another year.

DR. Z. L. SLAVENS.

## Original Communications.

### THE CONTINUOUS USE OF DIGITALINE IN THE VASOMOTOR AND CARDIAC LESIONS OF SENILITY.

BY HENRY BEATES, M.D.,  
Philadelphia.

Senility embraces that period of life during which one or more functions, as well as nutritional metamorphoses, when compared with the manifestations of the vital unit possessed by the individual, are recognized to be prematurely waning, and thus many are the instances of men and women who, being en-

dowed with vital energy sufficient to enroll them among the normal activities of advanced being, remain more or less disabled or invalided because of this premature failure of some special organ or system to adequately discharge function. This retrograde process has an insidious origin, manifesting itself much earlier in life than we are prone to imagine, and, primarily, as a rule, in the vasomotor system. This great system has not as yet received the attentive study it should, and its direct relationship to functional activity, whether it be of brain, special sense or organ, is such that it is not an exaggeration to state that life itself depends thereon.

Nutrition, then, active in the fullest sense

of the term, is the condition determining the normal relationship of function with vital unit and is intimately associated with the perfect fulfilment of vasomotor function, because the distribution of pabulum to each cell and organ is directly dependent upon the physiological integrity of this nervo-sanguineous system.

The first physiological symptoms of senility will almost invariably be found with some portion of the vasomotor system, and that which is most objective consists in pre-natural fulness of the superficial veins. This condition, of course, represents a far more advanced, although not visible, disturbance in the minute radicles, both of the arterioles and venules, and when present for some length of time, is associated with the symptoms of diminished function; therefore we have slight defects in intellection; the details of every-day life are forgotten, and the victim finds it necessary to utilize the memorandum tablet, instead of relying upon memory. Sleep is less refreshing, and is interrupted by slight insomnia. Some failure in vision and obtunding of hearing coexist. Respiration is habitually augmented in rate, and the ordinary activities of life, formerly free from any sense of discomfort, are now associated with more or less dyspnea. The digestive organs are all less active than before, and the disturbances especially noticeable are those accompanied with passive hyperemia and diminished absorption. The disturbances of the hepatic functions manifest themselves in paroxysms of headache and pruritus; the itching of the nose is especially noticeable, and is often contemporaneously present with similar annoyances located in areas of the back and lower extremities. This symptom is also an evidence of diminished supply of pabulum to peripheral sensory nerve terminals. Emaciation, while not marked, is pronounced, and the usual rotundity, characteristic of the vigor of life, gives place to the well known diminution in weight and wrinkling of the skin. The function of the sphincters, especially the vesical, is markedly impaired, and the passive hyperemia of the kidney gives expression to its existence by albuminuria often associated with casts.

The group of symptoms just enumerated, if the condition is well advanced, frequently assumes a clinical picture similar to that of organic disease, and thus has the writer seen what he believed to be senile softening of the brain, presenting a typical clinical picture, as

demonstrated by a failure to recognize the members of family, inability to realize living at home, and re-living boyhood life and oblivious to time and place, totally disappear under the treatment to be described—a fact demonstrating that the failure of functional activity may be due under these conditions, not to the death of the cell, but the absence of nutriment necessary to the maintenance of its vital phenomena. Of the cardiac conditions we have either fatty degeneration of the myocardium itself, cloudy swelling, or some type of retrograde change, either alone, which is exceedingly rare, or associated with gross lesions in the radicles and larger arteries.

Indeed, the changes in the cardiac muscle are, in ninety-nine cases of a hundred, *secondary* to a *primary* lesion of the peripheral arterial system. This fact is worthy of especial emphasis, and is to be considered in formulating a prognosis, other things being equal, with any given condition. Elsewhere will some facts associated with the physiology of the circulation be elaborated, and it will suffice in this connection to simply state that the *propelling* power of the arterial system, by reason of its vasomotor factors being diminished in senility and capable of being restored to the percentage longevity of vital unit involved, will result in the establishment of lost equilibrium. The symptoms associated with what has hitherto been considered "senile heart" are habitually augmented rate, diminution of resistance, and edema of the extremities; of course with these we have the bronchial disturbances, falsely called "asthma," and, in advanced cases, various forms of dropsy. The treatment of these cases with digitalis, alcohol, strychnine, strophanthus and nitroglycerin finds its limit of usefulness far down the scale of possible achievement, and the premature death of all such so afflicted has been the outcome of *secundum artem* methods.

It is taught that in the condition just described arterial tension is *increased*, and therefore digitalis should *not* be employed because by further augmenting arterial pressure it will produce apoplexy, and otherwise endanger the life of the sufferer. Careful study demonstrates that when the venous side of the circulation is tortuous and distended with blood, the arterial side possesses *less* than its normal, and while the aortic valves close with pronounced force, instead of its being the result of arterial tension, it is actually dependent upon the *weight of the column of blood*,

which, not being propelled by what may be considered vermicular contraction, fills the non-elastic vessel as if it were an iron pipe; therefore we have *weight* and not active force, and consequently *diminished* and not augmented arterial tension. What obtains in the aorta, is an expression of the whole arterial vasomotor system; consequently we have this disturbed circulatory equilibrium. The cerebral phenomena, so common in this condition, manifest themselves in their worst type, by symptoms suggestive of apoplexy, and not uncommonly does the patient complain of localized numbness, which after a shorter or longer duration culminates in confusion of thought, partial loss of consciousness, somnolency, loss or confusion of speech, and marked loss of power in groups of muscles.

This condition must not be confounded with true apoplexy, by which is meant rupture of a large arterial trunk, such as the middle meningeal or striate artery, because they are dependent upon either transient ischemias—that is, the terminal vessels failing to transmit blood to the part by reason of the lack of propelling power—or to actual ruptures of venous radicles, directly due to the overdistention characteristic of the venous side.

For years has the writer boldly treated these cases, with success, with heroic doses of this *special derivative* of digitalis, to be described.

The *continuous use* of the remedy is absolutely essential, because the senile condition underlying the causation of all of these phenomena is a permanently altered vasomotor system. The treatment with which these conditions have been successfully held in abeyance for years, and disabled life so improved that comfortable existence has been vouchsafed, is the exhibition of digitaline, and in doses necessary to produce the desired effect. The term “digitaline” is, by the shops, unfortunately employed to represent several active principles derived from digitalis, and as each one of these principles possesses an action peculiar to itself, many of which are diverse, it is evident why contradictory opinions prevail concerning the employment of this drug in this class of cases.

*Merck's German digitaline*, so called, is the drug the use of which for years has enabled the presentation of the above facts to be practicable. Chemically this is not “digitaline,” but what should be called digitalein;

it possesses a chemical formula of its own and is extracted from digitalis by a complicated process, after a tannate is first precipitated from an *infusion*. It is freely soluble in water and therefore especially adapted for hypodermic exhibition, and as it is only sparingly soluble in alcohol is present in the tincture in a correspondingly small percentage, and thus is seen the fact that it is a separate and distinct drug, as different from the other products as is morphine from arsenious acid. Its especial power is to restore the *propelling power of the arterial system*, whereby, secondarily, for obvious physiological reasons, the cardiac action approaches the normal, and thus is the circulation in the venous and arterial side balanced. This being accomplished, the vast group of morbid phenomena briefly indicated vanish. The doses necessary to effect this vary from the tenth as a minimum to one-half of a grain as the maximum, and must be exhibited from three to six times daily as the conditions demand. A number of cases have been taking this quantity for several years, and have presented no injurious consequences whatever.

If digitalis were used so unremittingly it might produce a cardiac hypertrophy; this is mentioned because the possibility of such an undesirable accident has been advanced as an argument against the continuous use of digitalis (crude drug).

Careful clinical study, having in view the detection of such a condition, with the use of digitaline, finds that the frequently increased area of cardiac dulness diminishes; therefore, other things being also considered, it can be legitimately concluded that hypertrophy is not produced by such method of administration. Again, various degrees of rigidity of the larger arteries, so commonly detected in advanced conditions of senile vasomotor disturbances, have largely vanished under the continuous use of the drug, and when the function of the artery is considered it is not difficult to understand that the “sclerosis” of the vessels, when not due to calcareous infiltration or atheromatous changes, is a true thickening and rigidity of the arterial walls, comparable with a similar process always present in the ligaments and capsules of a joint not functionally active, and, just as in the latter, when normal motion is restored, in the former we have, by reestablishment of the expansion and contraction necessary to calibration, nutritive activity operative, and normal plasticity of structure effected. When

normality is reestablished, it can be maintained by the continuous use of digitalein, just as long as the unit of vitality is endowed with time existence.

After the results above described have been secured, judgment and skill will determine a modification of the plan of administration of this valuable vasomotor agent. As a rule, after months of uninterrupted use of large doses, the tissues involved have reacquired that degree of normality which makes practicable the continuous exhibition of smaller doses, in order to maintain the restored circulatory equilibrium.

### *THE ETIOLOGY AND TREATMENT OF LARYNGEAL TUBERCULOSIS.\**

By P. S. DONNELLAN, M.D.,

Graduate of the Royal College of Physicians and Surgeons, Ireland; Fellow of the College of Physicians, Philadelphia; Laryngologist to St. Mary's and St. Agnes' Hospitals, Philadelphia.

The presence at the clinic to-day of three cases of laryngeal tuberculosis, each presenting a different stage of the disease, gives me the opportunity to make some observations on its etiology and treatment. Before we examine the patients I wish to refresh your memories with a few remarks on the diagnosis of tubercular laryngitis in order that you may better appreciate the importance of studying carefully each individual case, and of instituting a method of treatment exactly suited to it, for in no pathological condition is the avoidance of routine therapeutics more desirable than in tubercular laryngitis.

All competent observers agree upon the extreme rarity of primary tuberculosis of the larynx. In the majority of instances it is a local manifestation of preexisting tubercular disease in the lungs, or occasionally in other organs contiguous or remote. Before we enter upon the study of the diagnosis and treatment of laryngeal tuberculosis, let me briefly refer to the pathology of the disease. Accepting the theory of Koch that it is due to the invasion of the larynx by the tubercle bacillus in an individual who, by heredity or by environment, is liable to the disease, or whose resisting power has been enfeebled by previous illness—notably of the respiratory tract—we can readily understand how infec-

tion may take place; tuberculosis of the lungs being followed by that of the larynx, or, in those rare instances when the latter is the seat of the disease, the secondary involvement of the lungs takes place in a few weeks or months.

In the limited time at my disposal it is impossible to give even an outline of so vast a subject as the morbid anatomy of tuberculosis, so I will content myself with a brief description of the different forms of the disease as seen with the laryngoscope. Many authorities—notably J. Solis Cohen of this city—have drawn attention to a decided anemia as the earliest sign of laryngeal tuberculosis. This we can very readily verify in one of the patients whom I will presently show you. It seems to be an evidence of the general feebleness of the patient. Infiltration is usually the earliest local sign of the disease. It generally begins in the interarytenoid space, in one or both arytenoids, or in the epiglottis, but as Lennox Browne has pointed out, in patients whose profession involves much use of the voice the swelling may first be seen in the vocal cords and ventricular bands. In more advanced cases typical tubercular ulcers are observed. These ulcers are small, superficial, "mouse-nibbled," and as a rule are the result of breaking down of infiltrated areas. They are noticed most frequently on the arytenoids or on the laryngeal face of the epiglottis, and the presence of numerous tubercles on their surfaces indicates their true character.

Turning our attention to the symptoms of the disease, we find that some impairment of the voice is the first noticed. This may vary from a slight hoarseness to a complete aphonia, depending on the site, extent and character of the local lesion. Cough is almost always present, and from its frequency and paroxysmal character causes great prostration. It results from irritation produced by the local lesion, or reflexly from the pulmonary complications. Expectoration, which is slight at first, becomes purulent in advanced cases, especially when the lungs are much involved. Hemorrhages from the larynx are rare in tubercular disease, but occasionally occur after a paroxysm of coughing, which causes a rupture of one or more laryngeal capillaries. Dysphagia is probably the most distressing of all laryngeal symptoms, and if unrelieved causes rapid emaciation and invariably hastens the fatal termination of the case. It is so extremely painful when ulcers have formed on the epiglottis that patients

\* A clinical lecture delivered at St. Agnes' Hospital, June 25, 1898.

who have developed this complication will refuse even the most bland diet rather than undergo the agony which swallowing entails.

In the treatment of laryngeal tuberculosis constitutional measures must not be lost sight of, and every effort should be made to increase the power of resistance of the patient. With this object removal to a dry climate of moderate elevation and equable temperature should be urged. The patient should live in the open air and sunlight as much as possible, and take an abundance of animal food, eggs, milk, and fresh vegetables. Suitable exercises should be insisted on, and when the opportunity occurs massage carefully applied will be found of value in improving the nutrition of the patient. General hygiene should have proper attention—in a word, the sufferer should be placed in the best possible condition to insure the restoration of his health. Certain symptoms not directly referred to the larynx require appropriate treatment. Of these cough, dysphagia, night sweats and diarrhea are the most prominent. Cough can generally be controlled by insufflations of morphine,  $\frac{1}{4}$  grain, with 10 grains of powdered acacia, applied to the larynx with a powder-blower every four or six hours; or, if this is impracticable, the following prescription will be found of service:

℞ Codeinæ sulphatis, gr. iij; ,  
Sodii bromid., gr. 120;  
Syrupi Prun. Virginian., f 3 iv;  
Aque, q. s. ad f 3 ij.

Misce et Sig.: A teaspoonful every four hours for cough.

Night sweats are relieved by fifteen-grain doses of camphoric acid taken an hour before bedtime, as recommended by H. A. Hare, or, where insomnia is also present, by ten-grain doses of sulphonal in hot milk about three hours before bedtime. Diarrhea can be checked by careful attention to diet and by ten-drop doses of aromatic sulphuric acid every two or three hours, combined with half a drachm of paregoric if much pain is present. Dysphagia is usually relieved by the local application of cocaine, either in the form of a spray or with a brush, the four-per-cent. solution being a useful strength. Wolfenden's method of feeding—the patient being placed in the Trendelenburg position while he sucks liquid nourishment through a tube—will sometimes be found of service. In extreme cases rectal feeding will have to be employed until the larynx is improved by local treatment sufficiently to allow the passage of food over the epiglottis.

The local treatment of laryngeal tuberculosis has materially improved in recent years, because our knowledge of the pathology and morbid anatomy of the disease has become more accurate, and our therapeutic resources more extensive and rational. Previously all cases were treated locally with caustics in varying strengths, regardless of the condition of the larynx, or of the distress caused to the patient by their application. It was soon recognized, notably by Bosworth, that a soothing method of treatment was indicated, and caustics were abandoned for cleansing sprays followed by anodyne insufflations, resulting in much benefit to the patient.

A distinct advance in laryngeal therapeutics was made when Krause advocated the local use of lactic acid in the treatment of tubercular laryngitis. The patient's larynx having been cleansed by a spray of Dobell's solution, and a four-per-cent. solution of cocaine having been applied to the affected area, the ulcers are thoroughly rubbed every third or fourth day with a solution of lactic acid, varying in strength from twenty per cent. to eighty per cent. The applications are best made with a laryngeal cotton applicator. The improvement is at once manifest, and I have notes of several cases where, by this treatment, the ulcers healed perfectly. Even in cases where the lung involvement was very advanced, it should be advocated, as, although a cure may not be expected, the relief to the patient is usually very great. Herying has recommended curetting the ulcers before the lactic acid is applied in order to remove the necrotic tissue and thus secure a more thorough action of the acid.

Donelan published an article in *The Lancet* (London) in December, 1897, describing a syringe he had specially devised for the sub-mucous injection of minim doses of pure guaiacol into the tubercular infiltrations of the larynx preceding ulceration. He has had marked success in several cases from this mode of treatment, which seems to have the advantage of not producing areas liable to secondary infection from tubercular sputum, as sometimes results when the curette is used. Early tracheotomy has been advocated by some authorities on the ground that absolute rest of the voice is insured, and topical applications are more easily made, but is condemned by others, who deny that these results are obtained in their hands. It is, however, admissible in impending suffocation.

# NOTE ON A SIMPLE METHOD OF CURING APHONIA.

BY ALBERT ABRAMS, A.M., M.D.,

Professor of Pathology, Cooper Medical College, San Francisco.

For the relief of aphonia and dysphonia of laryngitis, no method equals the following: First mark approximately with a pencil on either side of the neck the point in the thyrohyoid membrane where the internal laryngeal branch of the superior laryngeal, the nerve of sensation to the larynx, passes into the latter organ. Over the points marked with the pencil freeze with chloride of methyl or a spray of rhigolene. Freezing must be thorough. The relief in most instances is almost instantaneous, and phonation, which was before difficult or painful, can be performed with perfect freedom. The relief thus afforded is of signal advantage to many professionals. In some instances the relief is of short duration only, in which cases freezing must be done again or several times.

I have used this relatively painless method for at least six years, and the results in most instances have been phenomenal. This same method may be employed with advantage in neuroses of the larynx, like laryngismus stridulus, spastic aphonia, and in the laryngeal crisis of tabes dorsalis. The use of any therapeutic agent based on empiricism alone will yield clinical results wholly at variance with strict scientific inquiry. I have therefore endeavored by theory and experimentation to evolve the rationale of congelation as a therapeutic agent. The following hypotheses are presented:

1. Freezing may act as a counter-irritant and the results achieved may be due to local or reflex action.
2. Freezing may act by producing physical changes in the underlying structures.
3. It may act as a shock.

The first hypothesis may be contravened in part on the assumption that freezing, unlike counter-irritation, is immediate in its action, of greater potency, and followed by slighter reaction. We know, however, that the application of cold to the superficies of the body induces through the automatism of reflex action contraction of the arterioles, especially in parts subject to inflammation, thus materially inhibiting the process of inflammation. The degree of cold secured by the usual methods of freezing is neither of sufficient intensity nor duration to warrant such a postulate. The reduction of tempera-

ture, as I have determined by experiment, is never sufficiently great to firmly sustain the first hypothesis. By *reenforced freezing*,\* which I have described elsewhere, a reduction of temperature to the freezing point may be secured.

The second hypothesis may be disposed of by briefly citing the results of certain experiments. If the skin over the large nerves of rabbits is frozen daily and the nerves afterwards examined, no degenerative changes in the latter can be demonstrated, and it is only after freezing is carried to an inordinate degree and repetition, unlike its clinical application, that any degenerative nerve changes can be demonstrated; and this degeneration, I have observed, involves not only the nerves, but likewise the superimposed tissues.

I am inclined to accept the final hypothesis as the most probable, viz., that freezing acts as a shock, inhibiting the nerve functions for a variable period. While conductivity is an expression of physiological nerve activity, pain or disturbed function is an expression of pathological nerve activity. The inhibition of the activity of a pathological nerve expresses the ideal attainment of therapeutics. This is secured remotely by analgesic or directly by local medication. The latter is the more rational method and can be attained by freezing, which, acting like a shock, inhibits the functions of the nerve, thereby putting it in a condition of rest.

784 GEARY STREET.

## THE VALUE OF SYSTEMATIC PHYSICAL TRAINING IN THE PREVENTION AND CURE OF PULMONARY TUBERCULOSIS.†

BY E. FLETCHER INGALS, M.D.,  
Chicago.

The absence of systematic study by physicians and the very meager literature compels me in this paper to be more or less dogmatic, yet there are numerous recognized facts that seem to justify calling attention to this subject, notwithstanding the absence of careful clinical observations.

One of the most common observations made by medical men is that the long, narrow, flat-chested individual is the one who is most liable to the development of tubercu-

\**American Medico-Surgical Bulletin*, December, 1895.

†Presented to the American Climatological Association, September, 1898.

losis; and we have all observed that in patients presenting this form of chest the chances for recovery are reduced to a minimum. This single observation is sufficient to suggest that systematic physical training, which would develop the respiratory muscles, expand the thoracic walls, and correspondingly increase the pulmonary capacity, would be of great service, not only in preventing tuberculosis, but in curing its early stages.

Pathology teaches that the collapsed air cells furnish a most favorable nidus for the development of the tubercular process; therefore, for prevention of the disease, we should adopt measures to expand the lungs and bring the air cells into the best possible working condition. It is probable that in most cases there is a pretubercular, or at least an early tubercular, localized anemia which, by diminishing the nutrition of the parts, lessens their resisting power and makes them peculiarly susceptible to the malign influences of the tubercle bacilli and the toxins which they produce.

From the wide-spread prevalence of tuberculosis, which is said to affect eighty per cent. of the human family, it is probable that all of us are at times infected by the Koch bacillus, but so long as the general and local resistance is adequate it is harmless, and the disease can make no progress. This hypothesis is supported by the fact that, notwithstanding the large percentage of people affected by tuberculosis, the majority of them recover. Even when the disease attacks the lungs, organs in which the conditions for the spread of the process are peculiarly favorable, it does not prove fatal in more than about twelve per cent., whereas we have good reason to believe that from thirty-five per cent. to forty per cent. of the human family are at one time or another affected by pulmonary tuberculosis. In most of those who recover the disease has made but little progress and it is only at the autopsy, after death from other causes, that its presence is detected. If these views are correct, it is clearly our duty to those whose health and lives are placed in our keeping to recommend measures likely to strengthen the resisting power of all the body tissues, but more especially those of the lungs, because they afford the most favorable conditions for the spread of the disease.

Tuberculosis attacking the skin and the bones is so limited by the natural processes that even at its worst it often extends over many years, and in many cases Nature throws

up an efficient barrier about the infected tissues which prevents extension, and ultimately recovery takes place. Similar processes should be encouraged in the lungs. It is now commonly believed that a high altitude affords the best condition for the prevention of pulmonary tuberculosis and for the cure of its early stages. It is probable that in large part this beneficial influence is due to the increased distention of the air vessels, caused by the rarefied atmosphere and by the patient's efforts to more completely fill the lungs. This expansion of the air cells not only empties them of the noxious principles that if left to themselves would develop into a serious disease, but equalizes the pulmonary circulation and removes the localized anemia which may have occurred either as the result of the deficient functional activity of the part, of pressure, or of partial obstruction of the nutritive vessels. As a means, then, of prophylaxis, our first measure should be to teach the patient to breathe deeply; and as a means of curing the early stages of the disease (which amount really to a little more than prophylaxis for the remaining healthy portions of the lungs) the same methods are most important.

It is a matter of surprise, to those who have not given the subject thought, to find how superficially many people breathe and how little they know of this most important physiologic process. It is common to find persons who get quickly out of breath who would not do so if they only knew how to fill the lungs, and when to fill them during exertion. For this reason careful physical training is of the greatest importance, and physicians should see to it that their patrons do not neglect any of the precautions which may give their lungs the best resisting power.

One of the first injunctions we should place upon the patient who has any reason to anticipate the development of pulmonary tuberculosis is that he should expand the lungs thoroughly several times every day. We must also personally inspect his mode of breathing to see that he knows how to carry out our instructions. In order to expand the lungs the patient should be directed to draw in the abdominal walls and take a long, deep breath, while the shoulders are carried gradually backward, and the ribs and sternum elevated as far as possible; he should hold this breath for a few seconds and then blow it out slowly and forcibly through a small opening between the lips. In this way not only the air cells

which can be reached by direct inspiration are inflated, but also those at the apices and along the borders of the lungs, which otherwise might not be distended. One has only to try this method a few times when out of breath after active exercise to ascertain how much more effective it is than the ordinary method of respiration employed by those who have had no physical training. By a few deep respirations such as just described, the healthy individual who has exhausted his breath will find that he can speedily recover it; whereas, by the usual respiratory efforts, he will pant for several minutes before he can obtain relief.

I have referred to the fact that the long, narrow, flat-chested individual is most likely to contract consumption and is least likely to recover from it. The questions arise: First, can systematic physical training cause any considerable change in the form of such a chest? Second, is such training beneficial after disease has actually developed? Without fear of contradiction, the first question may be answered in the affirmative. In the space of a few months such a person may generally be taught to expand the chest two or three inches more than previously, and after the exercise has been kept up for a sufficient length of time the form of the chest will be found greatly improved and the circumference increased very considerably. This, then, may be considered a most important prophylactic measure.

At Amherst College training is directed merely to securing general good health without attempts at feats of agility or even the development of powerful muscles. The records for twenty years show that in 2106 students who had exercise only half an hour four times a week, there was a gain of  $1\frac{3}{16}$  inches in chest measurement during their college course. At Bowdoin 200 students with the same amount of work gained an average of  $1\frac{1}{16}$  inches in chest measurement in six months. Archibald Maclaren (Physical Education) recommends for harmonious development: First, an introductory course of posturing and light exercise with dumb-bells and bar-bells; second, leaping, horizontal beam, vaulting (bar and horse); third, parallel bars, trapeze, swinging rings, ladders, horizontal bar, the plank, escalading; fourth, climbing the pole (fixed, slanting, and turning), the pair of poles, the rope, rosary and mast. By one hour's daily exercise in this way twelve young men from nineteen to twenty-eight years of age gained  $2\frac{1}{16}$  inches chest

measurement in eight months, and fifteen young men averaging eighteen years in four and a half months gained  $2\frac{1}{16}$  inches chest measurement.\* Although the increased chest measurement in these cases may have been partly due to natural growth, the rapid and pronounced development leaves no chance for doubting the effects of exercise, and we may safely answer that physical training may in a comparatively short time cause decided improvement even in the long, narrow, flat chest. These facts should also make us more persistent in our efforts to secure proper respiration in all those who are predisposed to pulmonary disease.

Slightly altering the second question, we ask, When tuberculosis has become established in the lungs, is it possible to check the process or promote recovery by physical development? This I think we may also answer in the affirmative. We know that the disease progresses from the original point of infection through numerous other foci, each commencing and spreading in much the same manner as the original infection; therefore, the more thoroughly the lungs are aerated, the greater resisting power will be acquired by parts still healthy but subject to infection, and the greater chance will Nature have to throw up barriers against the disease. Consumption is a disease of such long duration that in the majority of cases there is a period of several months during which by this means, aided by other measures, we may reasonably expect to check the process, and I may confidently assert that no small part of the credit in favorable cases must be given to pulmonary gymnastics.

It has been asserted that athletes are short-lived and that the majority of them die of pulmonary tuberculosis. Whether this assertion can be substantiated or not is an open question; but even if it is founded upon facts, we must take into consideration the further fact that the majority of professional athletes live very irregular lives, excepting for short periods when they are in training for some special event, and it is more than probable that with them early death or carrying off by consumption must be attributed largely to dissipation.

The examination of statistics from various colleges has shown that non-professional college athletes, in nearly all cases, outlive their expectancy as estimated by the most

\*Cheesman: Reference Handbook of the Medical Sciences, vol. ii, p. 759.

careful life insurance companies. Although a considerable number of these amateurs ultimately die of pulmonary tuberculosis, the percentage does not appear to be as large as among men who have had no physical training.

My friend, Dr. Otto T. Freer, who has assisted me in the preparation of this article by a very careful search of the journals and books in the Newberry Library and of such articles as appeared likely to afford any information in the library of the Surgeon-General's office at Washington, was unable to find anything of value bearing upon this subject, excepting in the monograph of Dr. John Ed. Morgan, entitled "University Oars," which was published in 1873. Out of 255 oarsmen who had rowed in the English University boat races, Morgan obtained replies to his letters from 251. These 251 were alive at the close of the year 1869. Thirty-nine old oarsmen had died; of these, seven died of consumption and two of other forms of chest trouble. Morgan says that, generally speaking, these cases were not of that physical vigor that a long boat race requires. One of these men burst a blood-vessel while rowing and died some years after of consumption. Another had consumption so many years after his rowing that there could have been no connection between the two. The next case died twelve years after the race. Morgan remarks that he may perhaps have injured himself. Another oarsman died of consumption four years after the race. Morgan's conclusions are that athletics tend to prevent consumption, but that people of delicate constitution should avoid training, as overexertion may possibly predispose to consumption; his statistics, however, do not appear to justify the latter conclusion.

In the *New York Medical Journal* of July 23, 1898, E. Palier quotes Jageras as stating that consumption is less common among gymnasts than others. Palier himself holds the common opinion that outdoor exercise is a good prophylactic, but does not consider chest development alone sufficient to prevent the disease. He cites the frequency of the disease among laborers and soldiers, but gives no statistics. In this connection I may state that consumption is a common disease among those living on farms, although it is usually supposed that they are more exempt than others. The fact of the matter is that consumption is frequent among all classes, and no one need expect to avoid it by following out any one method of exercise or by any one mode of life.

In "Diseases of Modern Life," Dr. B. W. Richardson inveighs strongly against "training" as done for physical contests and thinks athletes shorten their lives by it. He says nothing about phthisis, but attributes the evil effects of excessive athletics to heart strain. He says: "There is no sign, no evidence anywhere, that the greater culture of the physical strength has favored the longevity of an individual or the vital tenacity of a race." He thinks that excessive physical exercise insures premature decay and early death, and mentions the Jews as an example of a race of not a high physical standard, and of apparent feebleness of body, but he regards them of all civilized races first in vitality. On the contrary, it has been recently stated that the Jews are peculiarly prone to phthisis.

In estimating the good or ill that may result from systematic physical training, it must not be forgotten that the unfavorable statistics have been obtained from a study of professional athletes or at least from amateurs who have trained excessively. It is a well established fact that the firm muscles, the rounded chest and the large respiratory power developed in young men by moderate exercise are seldom lost even after the exercise has been suspended, but continue for many years or even for life with very little subsequent exercise; therefore, the importance to the young of proper physical culture, particularly of the respiratory muscles, cannot be overestimated.

As to the kind of exercise that is best for this purpose, it is probable that that recommended by Maclaren is as good as could be devised for its general effects. Nearly all forms of exercise that take the person out-of-doors, such as horseback riding, tennis, ball-playing, golf, bicycling, rowing, running, etc., seem well suited to improvement of the general health; but the methods that have seemed to me most suitable for continuous practise, and most beneficial for the development of the chest, are by Indian clubs, the rapid use of small dumb-bells, the horizontal bar, the trapeze, and boxing. In all of these the patient of necessity learns to breathe deeply and acquires strength of the respiratory muscles; but most important for our special purpose is the practise of frequent deep inspiration, whereby the lungs are thoroughly filled, and forcible expiration, which inflates the air cells at the apices of the lungs. This should be repeated several times daily. In order to secure regularity in this exercise

it is generally necessary to recommend for our patients some form of simple inhaler that may be carried in the pocket and used at stated intervals throughout the day. At the same time, according to indications, some stimulant or sedative inhalant may be advantageously employed for its effect upon the mucous membranes of the upper air-passages, but more particularly for its influence in securing regular use of the inhaler; for many persons will take some medicine regularly who would soon discontinue systematic inhalations of non-medicated air.

The inhaler that I employ is a simple hard-rubber tube about four inches in length and half an inch in diameter, filled throughout its middle two-fourths with corrugated blotting-paper, and having corks for each end so that it may be closed to carry in the pocket. The medicament is dropped on the blotting-paper and the patient is directed to take long deep inhalations through the inhaler every two hours during the day. After the instrument is freshly charged, the patient inhales but twice, two hours later four times, two hours afterward six, and at the end of the next two hours eight times. The instrument is then to be recharged. The patient is directed to draw in the breath deeply, to hold it for a few seconds and then expire forcibly with the lips nearly closed. There should be felt a sense of smarting or slight discomfort as low as the fourth rib, lasting from three to five minutes, after each inhalation.

The remedies that I employ consist mainly of thymol, menthol, tincture of iodine and formalin in solution of alcohol. Chloroform may be added to any of these to relieve cough. The inhaler is charged with from five to fifteen minims of the solution, according to the duration of the sensations which it causes. The strengths commonly employed are: Thymol, one to two grains to the ounce; menthol, thirty to sixty grains to the ounce; formalin, half drachm to one drachm to the ounce; and tincture of iodine, from two to four drachms to the ounce. Chloroform may be added in any desired proportion. I am satisfied that these inhalations are of signal value in the treatment of laryngitis and tracheitis, because by them the patient may make positive applications to the upper air-passages, which he could not do himself either by sprays or ordinary inhalations.

This method of treatment appears to me also of undoubted value in the prevention and cure of pulmonary tuberculosis, though I do not believe that these or any other

inhalants have any direct effect upon the tubercle bacilli; but they may mitigate the catarrhal inflammation of the mucous membrane of the upper air-passages that attends the tubercular process. The chief value of this method undoubtedly results from the deep respiration and consequent distention of the air vesicles and development of the respiratory power which is obtained by its use. Regular, systematic deep breathing cannot be secured with most patients unless some medicament be employed at the time, therefore it is best to use inhalants that cause well marked sensations and of known antiseptic qualities.

36 WASHINGTON STREET.

#### *APOCYNUM CANNABINUM*—"THE VEGETABLE TROCAR."

BY T. S. DABNEY, M.D.,

Late A. A. Surgeon U. S. Army, New Orleans, La.

The publication in your issue of June 15, 1898, of my letter in reference to the use of *Apocynum cannabinum* in dropsical affections has caused me to be inundated with communications from every section of the country. It is utterly out of my power to answer in full these letters, and as my stock of reprints of my original article, published in 1880, is exhausted, I feel impelled to furnish the profession, through your widely circulating journal, a rather complete history of a plant that has been discovered and rediscovered a dozen times—a plant growing wild from Canada to Mexico, from the Atlantic to the Pacific. I am especially impelled to contribute this article to the profession on account of my having had twenty years' experience with the remedy in question—a remedy scarcely mentioned in works on therapeutics and materia medica. Shoemaker devotes six lines to telling nothing about it. The last edition of the U. S. Dispensatory has about ten lines of misinformation about it. It says: "It is powerfully emetic and cathartic, sometimes diuretic, and promotes diaphoresis and expectoration." It neither promotes diaphoresis nor expectoration to any extent. It causes emesis and catharsis only when improperly used. It is the most powerful indirect diuretic known, and herein lies its great value in dropsies; and to its diuretic action alone is due the invigorating effect of this remedy.

Ascitic fluid, as is well known to all medical men, is highly albuminous, hence tapping

a patient is practically equivalent to bleeding him, and the greater the amount of fluid removed the greater the resultant weakness. Dropsical patients literally feed on the albuminoids contained in their closed cavities, and rapidly fail after several tappings. Purgatives act similarly by removing the albumen with the water; but when the ascitic fluid is forced through the renal filtering plant the albumen is halted and thrown back into the circulation, and the water alone is allowed to escape, thereby relieving the dropsy and feeding the patient, who has been slowly bleeding to death into one or more of his closed cavities. Hence it is that patients taking this medicine rapidly gain in strength in spite of its depleting effects. The appetite is usually rendered sharp, and this, coupled with the reabsorption of albumen, accounts for the rapid results so often obtained. It is not uncommon for a patient suffering from general anasarca to pass one or two gallons of urine daily, until the fluid is all removed and the patient resembles a dried herring.

Bartholow, Waring, Hare, Ringer and H. C. Wood make no mention in their works on materia medica of this unquestionably very valuable remedy. The cause for the expurgation of apocynum practically from the materia medica is easily found. Manufacturing chemists, through ignorance, carelessness, or greed, have foisted upon the profession a number of radically different drugs under the name of *Apocynum cannabinum*, hence results obtained by different physicians using different medicines under a common name varied so widely that the drug was eventually discarded altogether. The *Apocynum androsæmifolium*, an utterly worthless weed, is frequently substituted for the *Apocynum cannabinum*, which it very closely resembles in appearance. The leaves of the *Apocynum cannabinum* are single and sessile at the bases of the branches, whereas those of the *Apocynum androsæmifolium* are always in pairs. This is a marked difference, and should serve to readily distinguish one from the other.

Owing to the name of milkweed, by which this plant is widely known, many mistakes are made, for there are a number of totally dissimilar plants called in different parts of the country milkweed—*Asclepias incarnata*, for instance. It is also called dogbane, from its supposed anti-canine properties. Owing to the peculiar way the long slender roots of the plant have of crossing and twisting around each other, the name of "cross root"

has been given it by the Catholic Indians of Mississippi, whose simple faith sees the hand of God and the sign of the degradation of His Son in the flora and fauna everywhere. It was under this name of cross root that my attention was first called to it by a country storekeeper. I was told that Indians and negroes claimed it possessed great virtues in dropsy. I bought all the roots my friend had and requested a pharmacist in my neighborhood to make for me a strong tincture—one ounce of the roots making six ounces of the tincture. For three years I conducted experiments with this, to me, totally unknown remedy. The results obtained were so remarkable that Ward 24 in the Charity Hospital was set aside for the exclusive use of patients suffering from dropsical effusions.

At the end of three years of original experiments I was requested by a number of my colleagues to give my results to the profession. This I was willing and anxious to do, but what was the name (botanical) of my *crux radix*? After much trouble and expense, I succeeded in getting several living plants, which were transplanted in my yard, where they remained until they flowered, and then, and not till then, did I realize that I was using *Apocynum cannabinum*. My paper was read before the New Orleans Medical and Surgical Association in December, 1880. The Indians all over this country seem to have been fully informed as to the virtues of this plant.

Dr. Rollin B. Gray, in the *New York Medical Journal*, 1894, vol. lx, claims that in 1820 his grandfather, Judge John Gray, of Chautauqua county, N. Y., acquired a knowledge of its virtues from the Cattaraugus Indians, who called it "Nunquot." The Judge is said to have had great success in treating dropsies. Through Judge Gray the virtues of the apocynum were made known to his sons, Drs. John F. and P. W. Gray, as well as his grandson, Dr. Rollin B. Gray, who used it as early as 1866. Drs. Valentine Mott, John C. Peters and the elder Flint are said to have had very great confidence in this remedy.

Dr. James P. Kimball, Surgeon-major U. S. Army, stationed at Fort Wingate, New Mexico, tells us (*New York Medical Journal*, 1895, vol. lxi) that it is in common use among the Sioux Indians in Dakota and Montana, and among the Cheyennes in Indian Territory. By these Indians it is used almost exclusively for the deadly bite of the rattlesnake. Powdered roots are laid on the point

of entrance of the fangs after the parts have been well scarified, and then an infusion of the roots is given internally. According to Surgeon Kimball he believes the results obtained are admirable. The Indians claim the cure infallible.

Dr. J. H. Lowery, in the *New York Medical Journal*, 1894, vol. lx, sets up a claim of priority in the use of *Apocynum cannabinum* in aortic and mitral disease. He claims to have commenced its use in 1890. In the THERAPEUTIC GAZETTE, 1889, is an excellent article on the use of this remedy in disease of the heart especially. The author, Geo. R. Murray, M.A., M.B. Cant., physician to University College Hospital, England, does me the honor of quoting at some length my article published in 1880. It will be seen that Dr. Lowery cannot substantiate his claim. Mr. Murray claimed that the greatest benefit of the remedy would be derived in cases of aortic regurgitation.

In 1869 Dr. Jewett read a paper before the New York State Medical Society on the use of *Apocynum cannabinum* in removing dropsies, after failure with all known remedies. This paper when published created a pronounced sensation, and the Doctor was soon overwhelmed with letters asking the source of his supply, etc., the writers invariably claiming that no such results as those given in Dr. Jewett's paper were obtainable from the *Apocynum cannabinum* of the shops. Dr. Jewett was fortunately able to furnish to all correspondents a limited quantity of the roots, which grew in abundance near his home in Canandaigua county, and soon the journals were filled with the praise of this remedy, so aptly termed by Rush "the vegetable trocar."

On May 18, 1875, Dr. Hutchins reported before the Medical Society of the County of Kings, N. Y., a case of general anasarca treated with *Apocynum cannabinum* obtained from three leading New York pharmacies, the result being *nil*. Within forty-eight hours after the patient had been put on the genuine drug furnished by Dr. Jewett, every vestige of water had disappeared. Under date of February 16, 1875, Dr. Jewett wrote: "An experience of thirty years in its use has given me unbounded confidence, if properly used."

Dr. Mark Andrews, of Waterproof, La., states in the *Medical Brief* for August, 1898, that he has used apocynum successfully for forty years. I can add that twenty years' experience in its use has given me absolute confidence in my ability to entirely

discard the use of the trocar whenever a tincture, fluid extract or infusion of the bark of the root of the genuine *Apocynum cannabinum* can be obtained.

In 1826 Dr. M. L. Knapp published in the *American Medical Review and Journal* an article on the valuable diuretic properties of this herb. He was followed in 1833 by Dr. John H. Griscom, of New York, who published in the *American Journal of Medical Sciences* a very elaborate article on the same lines laid down by Dr. Knapp. At that early date commercial rivalry was not so keen as now, and besides most physicians prepared their own infusions and tinctures from herbs and roots, whose purity they could personally vouch for.

Is it not a shame that so valuable a remedy as *Apocynum cannabinum* has become almost unknown, on account of the unscrupulousness of our manufacturing pharmacists, who do not hesitate to foist upon us, in and out of season, a vast array of their own synthetic products? Will not some great house undertake a careful study of the true and the spurious Apocynaceæ and then furnish the profession with a tincture, a fluid extract, solid extract, and possibly the two alkaloids, apocynin and apocynein, that have so far been separated and recognized? These preparations must be of uniform strength. Cascara sagrada, that most valuable of all remedies in certain forms of constipation, would have shared a fate similar to that of *Apocynum cannabinum* but for a certain Western firm that always insisted upon using the bark of the *Rhamnus Purshiana* itself and never any substitute. Cannot this firm, that has furnished so many absolutely reliable products, undertake the manufacture of a fluid extract of *Apocynum cannabinum*? If so, the profession can rely upon its purity and its unvarying physiological results.\*

---

\* The following is part of a letter on this subject recently received by the author from Parke, Davis & Co., of Detroit, Michigan: "We are pleased to inform you that we have had on the market for a considerable time past a fluid extract of the genuine *Apocynum cannabinum* Lin. We enclose you herewith one of our labels, which will doubtless be of interest to you. Being perfectly aware that the collectors of *A. cannabinum* are very likely to supply *A. androsamifolium*, we took particular pains some time ago to correspond with the very upright and reliable collectors whom we employ for the collection of this drug. We called their particular attention to the chances of confusion, and requested from them a distinct and categorical statement as to the genuineness of the supplies which we receive from them. In response we were assured that they were properly informed in the premises; that they were taking the utmost pains to avoid confusion of supplies; and that we

One of the most interesting and scholarly papers that has appeared lately upon the subject under discussion is from the pen of Dr. A. A. Woodhull, Colonel U. S. Army, stationed at Denver. On December 11, 1897, Dr. Woodhull contributed to the *British Medical Journal* an article on Apocynum. The eleven cases cited by him show clearly the characteristic action of the drug and its wide range, and I have not hesitated to avail myself of the valuable information in the Doctor's paper in this article. Indeed, I acknowledge now that I have unhesitatingly made use of all obtainable information on this subject. My main object in compiling such a long article and citing the names of so many physicians who have written on the same subject is to induce authors of books on materia medica, therapeutics and dispensaries to give this remedy its deserved recognition. My second object has been to induce some responsible manufacturing chemist to place a reliable preparation on the market.

Though many cases of general and local dropsies have come under my care within the past few years, I prefer to cite the first sixteen cases treated by me in the Charity Hospital of New Orleans, as these cases are of public record, and as they clearly illustrate the wide range of usefulness of the remedy under discussion. They are taken from a reprint of a paper read before the New Orleans Medical and Surgical Association, December, 1880.\*

CASES I AND II.—In March, 1878, in Wards 23 and 26 (Prof. J. B. Elliott's) I commenced using tinctura apocyni cannabini in ten-drop doses on two patients suffering from general anasarca due to Bright's disease. The patient in Ward 23 had been tapped many times. The usual diuretics and cathartics had been faithfully tried in both cases without any perceptible benefit. The stomach of the patient in Ward 23 became so irritable after taking the medicine two days that it had to be discontinued. A marked improvement, however, occurred in him, and he was able to leave his bed and return home. I

could depend upon the genuineness of the drug furnished us. Not content with this assurance from our collectors, we of course compel every shipment of *Apocynum cannabinum* to run the gauntlet of our drug experts and of our botanist before it is accepted and manufactured into fluid extract. Under the circumstances we feel that we have done our whole duty and have observed every possible precaution with a view of guaranteeing the therapeutic efficacy of our fluid extract."

\*For most of my notes I am indebted to Dr. David Barrow and Mr. D. H. Tucker (now Dr. Tucker), resident student Charity Hospital.

have not since heard of him. The patient in Ward 26 was entirely relieved in five days of all dropsy, and left the hospital believing his troubles over. He has not since been heard from.

CASE III.—George B., of Mississippi, was admitted to Ward 25 October 23, 1879. Patient was about twenty years of age, and presented that peculiar white appearance almost pathognomonic of chronic Bright's disease. The urine was heavily charged with albumen, and casts in abundance were found to be present. In November I took charge of the case, though I saw no hopes of any ultimate good. General anasarca was found. Patient did not pass more than six or eight ounces of urine a day. Professor Elliott informed me that the usual cathartic and diuretic remedies had been tried in vain.

Patient commenced taking gtt. xx of tr. apocyni cannabini, and in a few days gtt. xxx were administered. The urine soon became abundant, a quart or more being passed daily. Fifteen or twenty watery discharges daily were passed from the bowels. In a few days the edema of face, arms, legs and feet disappeared; a small amount of ascites alone remained. Examination of the urine showed no diminution in quantity of albumen or casts. The dropsy never returned, though the patient's stomach refused to tolerate the drug after an emetic dose of it had been administered. On December 26, 1879, the patient was discharged. I learned subsequently that he died soon after reaching his home.

CASE IV.—Albuminuria, due to cirrhosis of liver. Joseph McC., aged forty-four, native of Louisiana, was admitted to Ward 25, in November, 1879. Urine scanty and highly colored; filled with albumen. No casts. Ascites and edema of legs to enormous extent were present. Gtt. xx of the apocynum cannabinum were administered at once. A marked improvement was visible next day. In ten days no trace of dropsy could be found. The albumen persisted, but no casts were ever found. In about ten days more every trace of albumen disappeared, but it made its reappearance in small quantities in about five days. The urine became very abundant. His bowels acted freely. The medicine was discontinued on four separate occasions, and with the invariable result of the reaccumulation of the dropsy. In every instance the dropsy was entirely removed in four days. Patient was discharged in December, with no dropsy and no albumen.

On February 25, 1880, he returned as dropsical as ever. On March 1, 1880, all anasarca had disappeared. The apocynum cannabinum was suspended on March 1, and patient was put on liquor potassii arsenitis gtt. v ter die. On March 9, no trace of dropsy or albumen being present, the patient was discharged. I was informed by some of his friends a short time ago that he has never had any recurrence of his trouble.

CASE V.—Wm. W., aged twenty-nine, native of Alabama, farmer, was admitted to Ward 22, January 23, 1880. Patient had lived in the Louisiana swamps for many years. His constitution was shattered by malarial fevers. His spleen was found to extend beyond the median line. On admission the patient presented general anasarca; great puffiness under the eyes; a pale, anemic appearance. From four to five ounces of urine were passed a day. Pulse was hard, showing thickness of arterial coats, but it was very weak. Patient stated that several years before he had caught a severe cold, which was followed by acute pain in the loins, and dropsy. The urine was found to be full of albumen and casts. Patient complained incessantly of pain in his head and loins. This being a well marked case of chronic Bright's disease, I determined to take copious notes.

January 24. Patient was put on tr. apocyni cannabini, gtt. xx ter die, and liquor potassii arsenitis gtt. v, cinchonidia sulphate gr. v, ter die. January 25, no change was observable, except three watery passages during the night. January 26, urine very copious, catharsis moderate. Patient says he feels greatly improved. The ascites, which was enormous, is considerably reduced.

January 27. Marked diminution in size; diaphoresis and diuresis most copious. Bowels only acted twice during twenty-four hours. Pain in loins greatly reduced; continues in his head. January 28, patient passed several quarts of urine in the past twenty-four hours; two passages from bowels. Reduction continues; no pain in back, little in head; appetite voracious. Patient steadily gaining strength.

January 29. One passage; urine very free. To-day the arsenic and cinchonidia were discontinued. On the 28th the medicine was vomited by patient; since then ten drops, thrice daily, have been taken. Complaints of heartburn and pain in head and loins. Urine little above normal in quantity; skin dry and cold; three passages in twenty-four hours.

February 1. Complaints of skin having been hot and dry last night; intense pain in head and loins.

February 2. Urine copious; three passages; patient feels well. The patient not having had a trace of dropsy for many days, his urine being nearly free of albumen and but few casts being found, his appetite being excellent and his general health being good, he was this day, at his urgent request, discharged.

On May 11, 1880, the patient returned and was sent to Ward 24. General anasarca, loss of appetite and general debility brought the patient again under my care. Albumen and casts were found as abundant as upon his first admission. Patient passed not more than five ounces of urine during twenty-four hours; skin was dry and bowels constipated.

May 12. Patient was given his old prescription of tinctura apocyni gtt. xx ter die, and in addition one dose of forty grains of compound powder of jalap.

May 13. Twenty-five watery passages during past twenty-four hours; urine improved; skin moist; no appetite. Patient continued to have on an average twenty-four operations a day to the 17th, when the medicine was discontinued for twelve hours. On this day but little dropsy was present; urine normal and appetite good.

June 24. Patient left without my consent. When he left his urine contained but little albumen, but plenty of casts. The patient was strong and vigorous looking.

July 24. Patient returned to Ward 24 in same condition as before. The apocynum cannabinum soon removed all dropsy and caused the skin and kidneys to act well.

October 22. The patient has had no return of dropsy for two months. His urine is steadily improving; some days a mere trace of albumen can be found, on other days it is quite abundant; all casts have disappeared. Patient takes gtt. v of the tincture of apocynum once a day.

CASE VI.—Mitral regurgitation of the heart. Thos. D., aged eighty, negro, was admitted to Ward 32, March 15, 1880. Twenty drops of the tincture were ordered three times a day. The medicine was discontinued after three days, as no results, either good or bad, were obtained. As the medicine did not act as a tonic, diuretic, diaphoretic, or cathartic, my opinion was that either the nurse failed to give the medicine or else the patient did not swallow it.

CASE VII.—Acute desquamative nephritis.

Charles T., laborer, aged thirty-five, was admitted to Ward 26, April 9, 1880. Puffy under eyes; great ascites; edema of feet and legs; urine abounding in albumen, epithelial casts, and fat globules. Ordered a turpentine stupe, free saline catharsis and tincture of digitalis. In a few days *tr. apocyni cannabini* was substituted for the tincture digitalis. Only one dose of sulphate of magnesium was given, and the turpentine stupe was removed as soon as it had reddened the parts slightly. The dropsy disappeared in a few days. In ten days every trace of albumen, casts and fat globules had disappeared. The nephritis in this case seems to have been due to great exposure to cold and dampness.

April 22, 1880. The patient was discharged strong and vigorous. He seemed cured. No tidings of him since.

CASE VIII.—Subacute nephritis. Patrick C., nurse in Ward 24 for a long time. He is still the nurse there. Patrick is sixty years of age. On April 16 he presented the following appearance: Enormous general anasarca of some months' standing. Urine loaded with albumen and casts and very scanty in amount. Suffered greatly from dyspnea. On the 16th he was put on *tr. apocyni cannabini* gtt. xx *ter die*. April 17, 18, 19 and 20, urine steadily increased in quantity, and diminished in albumen. Dyspnea relieved and appetite restored. Dropsy greatly reduced. On May 4 no trace of dropsy, albumen or casts was found, on a careful examination. I forgot to state that the attending physician prior to me had tried in vain to relieve the dropsy by means of compound jalap powder.

Since May 24 up to date (October 24) the patient has continued well. I believe him radically cured. Patient took gtt. v of the apocynum for a month after all signs of disease had disappeared.

CASE IX.—Chronic tubal nephritis. Harry A., aged twenty-eight; paperhanger. Admitted to Ward 24, April 16, 1880. Patient passed one pint of urine daily, thirty-five per cent. albumen, casts abundant. General anasarca present.

April 17 he was put on apocynum, gtt. xx *ter die*. April 18, no improvement. April 19, slight improvement. April 20, 21, 22, 30, marked but gradual improvement. May 4, no dropsy, casts, or albumen. May 8, a faint trace of albumen; no casts. May 10, slight trace of albumen. Patient steadily gained in looks and strength from the first few days.

May 11, patient left, against my judgment, believing himself cured.

The patient was readmitted to the same ward on September 16, 1880. On admission he was suffering from general anasarca and anemia. Patient only passed about half a pint of urine in twenty-four hours. Urine loaded with albumen; casts abundant. Patient suffered greatly from nausea, cephalalgia, and other uremic symptoms. Old treatment was at once instituted; in addition, infusion of juniper and bitartrate of potassium was given occasionally. In a few days patient's urine became notably increased and uremic symptoms disappeared. The dropsy has gradually diminished, but is still not entirely removed. The albumen and casts have not diminished much up to date (October 29).

CASE X.—Enormous ascites due to cirrhosis of liver. No edema in upper or lower extremities. J. H. D., aged forty-two, farmer, was admitted to Ward 24, bed 359, May 11, 1880. Neither casts nor albumen were found in the urine. Patient was at once put on the apocynum. An occasional dose of compound jalap powder was administered. The patient upon admission stated that he had been confined to bed for several months by extreme debility. The ascites gradually disappeared. June 15, no ascites, patient was strong enough to walk about, having evidently gained greatly in flesh and strength since his admission. August 1, patient had a profuse hemorrhage, and sunk at once into a state of coma, and died the next day.

CASE XI.—Aneurism of ascending part of aorta. Carl W., aged fifty-six; came from Pensacola, and was admitted to Ward 24 on May 13, 1880. Upon admission patient was suffering greatly from dyspnea. He said he had "asthma," and had been treated for it in vain. His hydrothorax being excessive prevented my making a positive diagnosis at once; edema of legs and feet was quite marked also. Upon admission patient was unable to sleep without great uneasiness; appetite was bad. *Tr. apocyni* was administered in the usual dose; occasionally a jalap powder was given.

I forgot to state that the apex beat of the heart was one and a half inches to the left of the left nipple. It was also much higher up than normal. Hydrothorax of right side was greater than that of the left side. May 19, no dyspnea. Patient enjoys sleep and food. But little edema of lower extremities; hydrothorax much improved. May 29, all

dropsy gone; both lungs filled well; apex beat of heart in its normal place. Patient's appetite became voracious. He stated that his sexual passions were greatly excited. June 2, patient was discharged, having gained in flesh and strength greatly.

**CASE XII.**—Mitral regurgitation. George C., aged forty-six, sailor, from Algiers, La., was admitted to Ward 24, bed 362, May 30, 1880. As soon as I saw the patient I advised him to go home to his family. I was satisfied after my examination that a few months or weeks would put an end to his suffering. As the patient insisted on being admitted, I ordered tincture of digitalis. Next day I ordered the tincture of apocynum and compound jalap powders. June 3, patient's stomach was too weak for either food or medicine—great dyspnea and anorexia. June 5, fifteen drops of digitalis was ordered three times a day. June 6, stomach being settled, the apocynum in ten-drop doses was again ordered; 7th, 8th, 9th, 10th, considerable improvement; dyspnea all gone. For the first time for weeks the patient was able to sleep lying down; 11th, 12th, dropsy disappearing quite rapidly, but the irritable stomach prevents pushing the remedy.

June 13. Acute inflammatory rheumatism set in. The apocynum was discontinued, and salicylic acid in large doses substituted. June 18, rheumatism greatly improved. No reaccumulation of water since the apocynum was discontinued. Patient sleeps and eats well. July 24, patient left, having a trace of edema in the feet and legs only. I heard he died a few weeks afterwards.

**CASE XIII.**—Mitral obstruction. Willie, aged seven; transferred from Ward 18 to Ward 24 on June 8, 1880. Upon admission patient could scarcely breathe on account of the enormous ascites; edema of lower extremities great. Deeming the patient past all hope, I hesitated in prescribing. I, however, ordered one dose of five drops of the apocynum. Next morning the little boy died.

**CASE XIV.**—Mitral regurgitation. Wm. G., aged forty-five; admitted to Ward 16 on May 3, transferred to Ward 24 June 8. Great ascites and edema of lower extremities; dyspnea so great as to prevent the recumbent posture; patient had not lain down for three months. June 19, patient was discharged, free from all dropsy and feeling in fine spirits. A few pills of elaterium were administered during the first few days. The apocynum was used throughout. Patient was recommended to take five drops of the

tincture of apocynum three times a day to regulate the heart's action, and to prevent the reaccumulation of the dropsy. He did not follow my advice, so he was readmitted to Ward 24 on October 22, 1880. Since his readmission up to date (October 30) I have not used apocynum, but have kept him on elaterium and compound jalap powders. To-day the dropsy shows but little diminution, although the remedies produce free catharsis. In a few days I will try the apocynum, and I feel sure he will be entirely relieved in a few days.

**CASE XV.**—Christian W., aged thirty; Swiss; cook; diagnosis, chronic nephritis. Patient had been in the Charity Hospital before; also in the Nashville Hospital. His attending physicians in both institutions pronounced his case one of chronic Bright's disease. Patient was admitted to Ward 24, bed 352, June 30, 1880. Upon admission he was suffering from general anasarca; albumen and casts in abundance were found in his urine; urine scant. Ordered apocynum three times a day; also an occasional jalap powder. July 16, no anasarca; urine much increased, but casts and albumen still present. Patient's general health apparently fine; complains of erethism. July 23, no reaccumulation; urine not examined for albumen or casts since the 16th. Patient left unexpectedly to go to work. A friend of his informed me a few days ago that he continues well.

**CASE XVI.**—Chronic nephritis, accompanied by great anasarca. E. W. T., aged thirty-five, native of New Orleans, clerk, was admitted July 27 to Ward 24, bed 357. Urine contained forty per cent. albumen; specific gravity 1014. Under microscope granular, epithelial and hyaline casts were found in abundance; about twelve ounces of urine passed in twenty-four hours.

October 30. Patient's urine very copious; several quarts during the day; only a trace of albumen present; casts difficult to find; a slight ascites still persists. Within the past few days infusion of juniper and bitartrate of potash have been used as adjuvants to the apocynum, which has been used from the beginning; occasional doses of jalap were administered. The patient is still under treatment.

It will be evident to all from the above cases that in the removal of dropsical effusions I have not confined myself to any one remedy, but that I place the apocynum far above all other hydragogues, especially

in Bright's disease. I have not pretended to state that the apocynum exercises any specific action in Bright's disease, but it is worthy of notice that in almost every instance where it was administered in that affection marked diminution of albumen and casts occurred; and in some instances every trace of both disappeared. Whether or not this remedy exerts any peculiar influence over Bright's disease, clinical facts do not allow us to state positively. The following advantages, however, possessed by the apocynum should commend it to all physicians:

1. The small quantity necessary to produce free diuresis, emesis, or catharsis.
2. Its pleasant, aromatic taste.
3. Its fine tonic properties, which compensate for the depression consequent on free catharsis.
4. Its harmlessness—an overdose being speedily followed by free emesis.

With this remedy at our command, I conscientiously believe paracentesis to be, in most cases, unnecessary.

*Physiological Action.*—Dr. J. Rose Bradford has conducted a series of experiments to ascertain the physiological action of apocynum. Its principal action has been found to be on the heart. The heart of the dog was slowed down to two beats to one respiration, and even as low as three beats to two respirations. It will thus be seen that it is far more powerful than digitalis. No such results have ever been obtained experimentally from the use of digitalis, for the vagus becomes paralyzed before this point is reached. Apocynum strengthens the heart and increases its tone, so that it stops the heart of the frog in systole. In mammals the heart is stopped in diastole, though a massive dose may stop it in systole. Clinically it has been found to regulate in a marked manner the action of the irregular heart, but it *does not* slow the normal heart. It will be seen that it very closely resembles the action of strophanthus—itself one of the Apocynaceæ—digitalis, adonidin, caffeine, and sparteine, but it is the most powerful of the group. Its action on the arteries differs from that of digitalis, as is shown by changes in the blood-pressure. It causes no contraction of the arteries, hence no increase in blood-pressure. It therefore resembles strophanthus rather than digitalis in this respect.

Experiments carried on by Dr. Ringer, in University College Hospital, Cambridge, England, and quoted by Mr. Murray, sub-

stantially confirm the above. Dr. Sokoloff's investigations into the biological action of this drug, made in the clinical laboratory of Prof. S. P. Botkin, St. Petersburg, showed slowing of heart's action, enlargement of pulse wave, and *marked rise of blood-pressure*. It is not stated whether Dr. Sokoloff's experiments were made with the heart in a physiological or pathological state. Dr. Ringer's experiments were all conducted in the hospital and on patients suffering from cardiac disease.

According to experiments conducted by Petteruti and Somma (*Il Policlinico*, Nos. 10 to 14, May to July, 1894), far different results were obtained when the decoction was used instead of the tincture. The decoction seemed to act mainly on the stomach and intestines, promoting catharsis and emesis. When emeto-cathartic action was delayed, decided action on heart was noted and a resultant increased diuresis and acceleration of heart beat. The tincture was found to be free from gastro-intestinal irritant effects even when given in large doses.

Apocynin being soluble in boiling water and insoluble in dilute alcohol probably accounts for the nauseating effect of the decoction. Apocynin, on the other hand, is insoluble in boiling water, but soluble in alcohol. These authors claim: "A marked effect of the tincture is the production of diuresis, which is never accompanied with albuminuria; when albumen has been present, it has disappeared after a course of the tincture." This statement but confirms the same point made in my paper published in 1880.

It will be seen, then, that the two alkaloids isolated in 1883 by Schmiedeberg have different properties. It can now be stated as a fact that apocynum acts as a diuretic through its cardio-kinetic action and not by irritation of renal epithelium—a view claimed in my original paper.

#### THE USE OF SERUM-THERAPY IN POISONING BY MUSHROOMS.

*La Presse Médicale* of June 22, 1898, records the use by CLAISSE of serum-therapy in mushroom poisoning. He points out that the subcutaneous injection, as in ordinary hypodermoclysis, does much to relieve the characteristic symptoms of collapse or nausea, particularly if they are choleraic in type. In pressing cases intravenous injections may be given with advantage.

### THE OPERATIVE TREATMENT OF INTESTINAL PERFORATION IN TYPHOID FEVER.

This subject is one which interests the physician and the surgeon to an equal degree and deserves careful study by both, since in some cases life can be saved by prompt action.

There are no more interesting studies in medicine and surgery than those advances which meet conditions heretofore considered beyond relief, and there are few conditions more terrifying to the physician and to the patient's friends than perforation of the bowel in typhoid fever. Theoretically, at least, it would seem that with the progress which has been made in abdominal surgery operative interference is beyond all doubt the chief possibility for the recovery of the patient, yet as a rule both physicians and surgeons have in the past felt timid about resorting to so grave a surgical procedure in the face of the profound exhaustion of the patient from disease. In this connection the statistics which have been recently collected and published by Keen give us clearer ideas of our duty under these

circumstances than any others with which we are acquainted. One of the first points impressed upon us by these statistics is that delay is an exceedingly dangerous thing. Thus, as Keen points out, of the sixty patients operated on for perforation in typhoid fever, 26.7 per cent. recovered when the operation was done within twelve hours; whereas the mortality was total when as long as twenty-four hours had elapsed, except in three instances, in one of which the operation was done twenty-six hours after perforation and the other two between two and three days. As a result of these statistics Keen enunciates the law that if operation is not done within about twenty-four hours after the perforation there is practically no hope of recovery.

It is stated in *La Presse Médicale* of May 18, 1898, that Guecehewitsch and Wanach have recorded five instances in which Russian surgeons have operated for intestinal perforation. In 1891 Netschaieff and Troianoff operated upon a man aged thirty-one years, who presented signs of perforation. The operation was practised six hours after the entrance of the patient into the hospital. Marked evidences of serous peritonitis were found and fecal matter was in the peritoneal cavity. Resection of the perforated portion was performed. Death followed and autopsy revealed typhoid ulcers in the ileum. In 1893 the same authors operated upon a man of twenty-eight years, who presented similar symptoms. On entering the hospital a diagnosis of the ambulatory form of typhoid fever was made, with intestinal perforation. The operation took place seventeen hours after entrance. A general sero-purulent peritonitis was found, the fluid being filled with fibrinous flakes. Quite a large perforation was present; four centimeters of the intestine was excised. The abdominal wall was not immediately sutured, but the opening in it was packed with sterile gauze, and complete recovery followed.

A third case was that of Kohltzoff and occurred in a man of twenty-four years who had typhoid fever and congestion of the lungs. He had symptoms of perforation with excessive fever. The operation was performed four hours after the perforation. Sero-sanguinolent fluid was found in the peritoneal cavity, and twenty centimeters from the ileocecal valve there was a perforation. A resection of the perforated portion of the intestine was performed. Death occurred in two days. At the autopsy nu-

merous typhoid ulcers were found near the point of ulceration.

In the fourth case, belonging to Troianoff, a patient twenty-nine years of age had been sick for fifteen days with fever. He was seized with violent pain in the belly followed by intense chills, vomiting, and hiccough. There was abdominal swelling and general pain. The symptoms were those of perforative peritonitis. The operation began sixteen hours after the accident. Abundant seropurulent fluid was found in the abdominal cavity and perforation of the intestine had occurred ten centimeters from the ileocaecal valve. Resection of the perforated segment was performed and death occurred fourteen hours afterwards. The autopsy revealed typhoid ulcers in the ileum.

In addition to these cases Guecehewitsch and Wanach report five more. The first of these was a man thirty-six years of age, who had had typhoid fever fifteen days. After eight days he had had bloody stools, violent pain in the belly followed by intense chills, vomiting, and hiccough. The belly was swollen and the pain was general. The pulse was 120, the temperature febrile. An operation was performed two hours after the perforation. On exploring the intestines two perforations were found, one two centimeters in diameter, the other much smaller. Twenty centimeters of the intestine was resected, and death followed in about two hours. At the autopsy ten ounces of fetid pus was found in the belly. The parietal and visceral peritoneum were covered with punctiform hemorrhages. The part of the intestine resected was thirty-seven centimeters from the caecum. Their second case was a man of twenty-four years who had been ill some time with typical typhoid fever. Seven days after entrance into the hospital he was seized with violent chills and fever, and all the symptoms of perforative peritonitis. The operation was done seventeen hours after the accident, ether being given after a preliminary injection of cocaine. Perforation of the intestine was found. The mesenteric glands were enlarged and were adherent to the intestine in places. Thirty centimeters of the intestine was resected. Death occurred in six hours after the operation. The autopsy revealed profound typhoid ulceration at the lower extremity of the ileum. There were also signs of catarrhal pneumonia. The third case was in a young man of nineteen, who had been sick five days. His fever was high and he had bloody stools. Four weeks after

his entrance into the hospital he had perforation of the intestine. His condition remained grave, and on opening the peritoneal cavity it was found to be filled with bloody fluid and there were intestinal adhesions. Death occurred in three days. Again the autopsy revealed perforation and ulceration. A man of twenty-seven presented mild symptoms of typhoid fever. Six days after his entrance he was seized with violent pain in the belly and with chills and sweating. There was also meteorism. Twenty-four hours after these symptoms the operation was performed. Again the belly was found filled with seropurulent fluid. Thirty centimeters of the intestine was removed and contained four ulcers. Notwithstanding injections of saline solution the patient died eight hours after operation. Again the autopsy confirmed the diagnosis. In the fifth case a man of twenty-nine entered on the seventh day of typhoid fever; six days later violent pain in the caecal region came on with moderate fever. Surgical intervention took place thirteen hours after the accident. The abdominal cavity was filled with serous fluid. The walls of the intestine were edematous. Resection was performed. Death occurred in three days. The autopsy revealed the characteristic lesions and pneumonia of both bases of the lungs. Altogether these authors quote seventy-one instances of perforation in the course of typhoid fever, with seventeen recoveries. The number of deaths in operation for perforative peritonitis in typhoid is necessarily high. \*

In regard to the time for intervention it is evident that much depends upon the promptness with which the surgeon proceeds to the relief of his patient, and it would seem that good results are apt to follow only in those cases in which the intervention is immediate or where Nature has protected the peritoneum by inflammatory exudations which cause a limited peritonitis. In regard to the anesthetics which may be used in these cases, these two Russian surgeons believe that either chloroform or ether is satisfactory, provided the myocardium, the lungs, the kidneys, the liver, are in fair condition. In other instances they think that mixed anesthesia is well. They produce local anesthesia by cocaine and find that smaller doses of chloroform and ether are needed under these circumstances. Washing out of the peritoneal cavity in these cases is of the greatest possible importance, normal saline solution being employed.

### THYROID THERAPY.

It is not our intention in this editorial to discuss the good effects in myxedema and cretinism which follow the use of thyroid gland, but rather to consider the physiological action of the remedy in order to make its use less empirical and more rational. However certain may be the results obtained in disease by remedies of a given type, it is always necessary to determine more or less rapidly the exact method of their action, and when this is done it is sometimes found that they possess properties of still greater power in maladies in which heretofore they have not been tried.

In this connection a summary recently prepared by Robert Hutchinson and published in the *British Medical Journal* of July 16, 1898, is of interest, for his paper embodies a digest of what has been learned experimentally in connection with the effects of the thyroid. It has been found by a number of investigators that the use of this gland internally greatly increases the elimination of nitrogen, or in other words, that it hastens tissue waste in the proteid portions of the body, as for example the muscles. It is also a fact that under its effects a greater amount of oxygen is taken in and a somewhat less, but still increased, quantity of CO<sub>2</sub> given out. Which indicates that the gland causes a greater combustion of body fat, since the loss of body weight is greater than can be accounted for by the increased elimination of nitrogen. In other words, under the effect of the thyroid there is an increased rapidity of combustion throughout the body, while the increased urinary flow which follows its use decreases the patient's weight considerably as well. These scientific facts bring us face to face with the important question as to the real value of the thyroid in the treatment of obesity, for if it would decrease the patient's weight by eliminating fluid and burning up fat, and not at the same time cause the breaking down of muscular tissue, its value as an antifat preparation would be very great. This, however, is not the case, as we have already pointed out, and the practical lesson to be learned is that when treating obese patients by this remedy we should give them an increased amount of proteid foodstuffs to compensate for the nitrogenous breakdown associated with the loss of fat.

Another important effect of the thyroid gland is to hasten cell activity. Under its influence the life history of a cell is carried

quickly to its completion, and this may be one of the ways in which it does good in those diseases, like myxedema and cretinism, in which cell life is so slow that the cells never reach maturity in all its completeness.

Not only does this gland exercise the effects already named, but it also seems to prevent the body from utilizing all the fat-forming material which may be ingested. Thus if glucose is given in the dose of 100 grammes to a healthy man, it will not cause glycosuria, whereas if thyroid gland is given this amount of glucose cannot be used by the economy and glycosuria takes place (Bettmann). Upon the circulation the effect of thyroid gland is interesting. The blood-pressure is not directly influenced by it through the vasomotor apparatus, the slight fall which sometimes ensues being due to a depression of the activity of the heart. Upon the blood the effects vary. If the patient be in health the use of moderate amounts of thyroid gland produces no effect; if it is given in excess the blood cells are destroyed; but if it is given to a myxedematous patient the cells are greatly increased.

The process of its elimination, when thyroid is given, is slow.

### IRON AND OPIUM IN BRIGHT'S DISEASE.

These two drugs have been highly lauded by many writers in the treatment of patients suffering from Bright's disease, and it has been common for physicians to be carried away by empiricism to such an extent as to administer iron to all cases of Bright's disease, whether the condition of the blood indicated marked anemia or not. Further than this, iron has been given in quantities so large that even the healthy emunctories of the normal individual would be unable to handle it, not to speak of the impaired vital processes of one whose system is undermined by chronic nephritis. It has seemed as if in the wild desire to find something to relieve an incurable disease physicians had come to pour into their patients Basham's mixture, for example, because they could think of nothing else to administer.

In this connection an interesting article has recently been published by Dr. James Tyson, of Philadelphia, in the *Journal of the American Medical Association*, in which he well points out that iron has no specific curative effect in Bright's disease, and furthermore that it is often harmful by locking up secre-

tion and checking elimination. He even goes so far as to tell us that Basham's mixture, or iron in any form, may in his opinion even precipitate uremic symptoms. He also enunciates the view that iron is contraindicated in all cases of acute Bright's disease, and that chronic-interstitial nephritis is a malady in which the remedy in the vast majority of cases does harm rather than good. There is only one form of Bright's disease in which iron can be administered, namely, chronic parenchymatous nephritis, and even here it is to be administered with caution and small doses are to be given rather than large ones. Whenever the iron appears in the stools, showing that a considerable portion of it is unabsorbed, it is doing no good and probably harm, and the dose should be cut down or the remedy entirely withheld.

In regard to the question whether Basham's mixture is actually a diuretic, Tyson lends the weight of his opinion towards the side that indicates that this is an error. Indeed, he thinks that the bulk of water which is sometimes taken in Basham's mixture aids in the diuresis more than the iron which it contains, or at least the other ingredients increase the urinary flow.

These opinions, we may state, are entirely in accord with our own. We have never seen any rational statement as to why Basham's mixture should be poured into the throats of patients suffering from renal disease in the universal manner in which it is given, and we would urge upon practitioners the necessity of limiting its administration to that class of patients who seem to have comparatively slight renal lesions with an anemia which is out of proportion in its severity to the kidney trouble.

In regard to the use of opium in renal disease it may be stated that we here come in contact with a method of treatment which is not so commonly resorted to as is the use of iron, and yet which physicians largely employ, probably as the result of the high praise accorded to the action of opium in the treatment of uremia by the late Dr. Loomis, but, as Tyson points out, Loomis' views on this question have been much misrepresented, as may be seen on reading the item in the Progress columns dealing with this matter. Thus Loomis recommended injections of morphine for the uremia of acute nephritis, yet physicians in general have believed that he advised its use for all kinds of uremic convulsions.

Against the view that opium is useful in any form of uremic trouble Tyson makes a

stand, and while he does not condemn its use absolutely, he believes that opium is useful in a very limited class of patients, so limited that it is wise for the general practitioner to make a rule never to give it. Here, again, we think Dr. Tyson has done the profession and its patients a service in pointing out therapeutic errors into which many of us have gradually drifted.

---

#### SOME RECENT IMPROVEMENTS IN ASEPTIC TECHNIQUE.

---

In the sixty-seventh volume of the *Archives of Clinical Surgery*, second half, are found some able papers upon asepsis, the most important, thorough and immediately practical being that of Mikulicz, who after a brief review of the changes in method which have taken place since the time of Lister, and some words of commendation of the aseptic method as elaborated by Bergmann and made more or less practicable by the ingenious devices of Schimmelbusch, advances the opinion that the results, so far as the assurance of healing of all wounds is concerned, are yet so unsatisfactory as to render imperative careful attention to the minutest details of operative preparation, and a painstaking revision of them for the purpose of abolishing sources of infection commonly unrecognized or neglected.

As to the absolute sterilization of dressing material, this, of course, can be accomplished by heating. There is, however, no generally adopted method by which the surgeon can know with absolute certainty that the dressing which is handed to him has been subjected to a sufficient degree of heat to accomplish such sterilization. In a well managed clinic errors on this point are not likely to occur. Still, it is always possible that they may. As a means of enabling the surgeon to be positive on this point Mikulicz suggests the following: A strip of unsized paper is marked with the word "sterilize" and is then painted over with a three-percent. starch paste. When half dry it is again painted with a potassium iodide solution, made by adding one part of iodine and two parts of potassium iodide to one hundred parts of water. The strip at once becomes of such a dark blue color that the writing is completely concealed. In hot steam this dark blue color disappears, or at least to an extent sufficient to enable the writing to become distinct. Dry heat will not accom-

plish this result. Under pressure in an apparatus in which the steam is raised to a temperature of  $106^{\circ}$  C. the strips which are hanging free are decolorized in ten minutes; those which are placed in the middle of a dressing not for twenty minutes or over. If the temperature is less than  $100^{\circ}$  C., more than an hour is required for the decolorization. The strip of paper thus prepared and placed in the center of a dressing proves positively that the dressing has been subjected to hot steam and not hot air, that the steam has been sufficiently hot for thorough sterilization, and that it has operated for a sufficient length of time. Experimental research has shown that even the most resistant bacteria are destroyed before decolorization of paper thus prepared.

As to the sterilization of sutures and ligatures, the present methods are absolutely satisfactory. The main points to be considered at present are as to the advisability of impregnating catgut with some material such as iodoform which inhibits germ growth, and the choice of a method of sterilization which renders the gut strong and easy to handle. Mikulicz prefers the Hoffmeister catgut, and states that he is in every respect content with it, that he never noted suppuration which could be traced to its use. It should be noted that according to Poppert, both catgut and buried silk sutures may occasion sterile suppuration. Hoffmeister's method is described by Vinberg (*American Gynecological and Obstetrical Journal*, June, 1897) as follows:

The gut is first immersed in a solution of formalin of from two to four per cent. according to the size, and allowed to remain in this solution for a period of from twelve to forty-eight hours. The formalin is then removed by washing in running water for twelve hours. It is then boiled in water for fifteen minutes, after which it is transferred to a vessel containing alcohol, where it may be kept until required for use. Carbolic acid in the proportion of two to four per cent. is added to the alcohol and makes the gut more firm, but it should be removed to plain alcohol some time before using. The secret of success in this method of preparation is to keep the gut in a high state of tension until after it has been boiled. Hoffmeister recommends that the gut be rolled tightly on glass; and Lange, of New York, has devised a small steel frame for this purpose.

The instruments are satisfactorily prepared by boiling in soda solution.

Infection, difficult or sometimes impossible to avoid, may arise from three other sources, namely, the air, the skin of the operative area, or the hands of the surgeon or his assistants.

The importance of air infection, at first greatly exaggerated, has latterly been too much neglected. It is true that the bacterial forms found in the air are most of them non-pathogenic and are of minor importance, excepting in and about hospitals where there may be large numbers of pathogenic micro-organisms floating about. This is particularly true of large lecture halls, where the ratio is markedly increased by the coming and going either of students or assistants. In small operative rooms the ordinary methods of cleaning and preparing are practically efficient, but to prevent the bringing in of bacteria by outsiders it is requisite that each should be covered with a perfectly clean mantle, and, a matter of greater importance, that each should put on rubber shoes, which have been previously cleansed and placed on a surface moist with sublimate. This is especially important in the case of medical students coming as they do from the dissecting rooms, pathological departments, and hospital wards, and bringing in on their shoes enormous numbers of virulent bacteria.

A much more important source of infection than that from the air of a room is that from the mouths of the operator and his assistants. It is sufficiently proven that in the mouths of perfectly healthy people pathogenic bacteria are found and these bacteria are virulent. Of forty-eight healthy persons examined, in one-third were found virulent yellow pus staphylococci. In the mouths of those suffering from ordinary sore throat, streptococci were found thirty times in forty investigations; staphylococci seventeen times. The majority of these micro-organisms were virulent. It is noteworthy that not only are the number and variety of the mouth organisms markedly increased by slight pathogenic processes such as sore throat, but also their virulence is greatly augmented.

In ordinary talking these bacteria are carried from the mouth in sufficient quantities to produce infection, whilst in clearing the throat, coughing, or sneezing, they are projected for the same distance in enormous quantities. Hence it is evident that some means must be taken to prevent these bacteria reaching the open surface of a wound, and this is particularly important when the surgeon has any inflammatory condition of his mouth or nostrils.

This protection is afforded by a double layer of gauze bound about the mouth and nose, or better, by a mask in the form of a chloroform mask, so fastened that breathing is easy. Investigation has shown that such a mask absolutely prevents the escape of bacteria while the surgeon is breathing ordinarily or talking, but that in clearing the throat or coughing it does not provide an absolute protection, whilst in sneezing the protective worth of the mask is extremely slight. Mikulicz has used such a mask for six months and states that he is so accustomed to it as to wear it without inconvenience.

Thus, by thorough previous cleansing of a room which has been specially devised for operations, by clothing all who come in and go out of that room with sterilized garments and putting on them rubber shoes, and by placing on the surgeon and his assistants gauze masks which prevent infection from the mouth, the possibility of infection from the air is reduced to a minimum.

The disinfection of the skin covering the wound area is a more difficult matter. It is proven beyond controversy that none of the disinfection methods are able to destroy the germs lying in the deeper layers of the skin. Alcohol and sublimate are somewhat more potent than carbolic acid and sublimate, but both fail in about fifty per cent. of cases. The important point, so far as infection of the wound is concerned, is, however, superficial disinfection. This is best accomplished by the thorough use of soap and water before the employment of alcohol and bichloride. Because of the impossibility of sterilizing the deeper layers of the skin it is important to keep the superficial layers protected so that they may not be rubbed off and thus expose the hands of the surgeon, the compresses and the instruments to infection. If the skin is affected with eczema or acne, or has developed in its substance pustules, operation should be postponed if possible. If not, Mikulicz first cuts through the skin and superficial fascia, then secures by means of long sharp tooth forceps a slit compress to the edge of the wound, not including the skin.

Although the stitching of healthy skin but slightly endangers infection of the wound during operation, it may occasion infection during healing by the medium of the stitch canal. Many stitch abscesses are caused by bacteria lying in the deeper parts of the epidermis. When the stitches are deep the infection may thus be carried to the depth of

the wound. The danger of these abscesses is lessened by using very fine suture material and by not placing tension upon the stitches. Where tension sutures are required they should always be buried beneath the skin and a fine, loose, accurate running stitch should be used for superficial closure. Examination of the stitches removed at the time of the first dressing, usually in from four to eleven days, showed that very few were entirely sterile. *Staphylococcus albus* was usually present; in about twenty per cent. of the cases it was combined with the aureus. In the secretion of a few stitch abscesses no micro-organisms were found, and there were many cases of primary healing in which both the albus and aureus were found in the silk removed. There was one case of severe infection caused by the albus.

Drainage distinctly increases the danger of infection from the skin, and this danger can only be avoided by doing without draining. Since the bacteria of the deeper skin layers cannot be destroyed, Mikulicz advises the impregnation of suture material with an inhibiting agent, preferring for this purpose iodoform. Immediately before the operation he lightly paints the skin of the operative area with a tincture of iodine, holding that this agent exerts a protracted inhibiting force upon the skin bacteria, and finally, after closure of the wound, he covers it with zinc paste, thus preventing entrance of bacteria from without.

The sterilization of the hands is the most difficult problem of all. The most thorough and elaborate procedures have proven inefficient. Moreover, investigations show that individuals vary greatly as to their ability to cleanse their hands, some with apparent ease and in a short time approaching a degree of sterility which others seem quite incapable of reaching after prolonged efforts, and this to a certain extent was independent of the previous degree of infection of the hands, though it was noteworthy that in those who had to do with the operating upon and dressing of septic cases virulent pathogenic germs were always found.

Although it is true that in perhaps a large percentage of cases before the operation the hands may be superficially freed of germs, this does not last long. During the course of the operation the germs which lie in the deeper skin layers reach the surface in increasing numbers. Thus it follows that the danger of infection of a wound from the hands is greater in proportion to the length of the

operation, and hence some form of sterile covering to the hands is indicated. This protection is provided by sterile gloves, but not completely. Experimental research has shown that during the course of an operation the germs from the skin of the hand will pass through these gloves. None the less, the percentage of successes in surgery was markedly increased in Mikulicz's practise by the use of gloves, having risen from eighty-three to ninety-four per cent. He holds that generally the wound is infected by the finger points and the nails. To lessen the danger from these sources he paints around the nails and beneath them pure tincture of iodine, then dips the finger ends in the same solution. After that he washes his hands in lysol and then puts on his gloves. This application does no harm to the fingers. In long operations the gloves should be frequently changed. This is especially true in operations in which they become soaked with blood.

As a rule wounds should be closed without drainage, or there will result in about ten per cent. of the cases hematomata, which either have to be aspirated or are absorbed very slowly. If this formation is likely to occur, drainage should be continued for twenty-four hours; cases of thyroid extirpation are always drained for this length of time by Mikulicz.

---

## Reports on Therapeutic Progress

---

### ULCERATION OF THE STOMACH.

DUNCAN, in the *Intercolonial Medical Journal of Australasia* of March 20, 1898, says that in France, at least, this malady is receiving a great deal of surgical attention. M. Hartmann, at a late meeting of the Société de Chirurgie, gave his experience of the treatment of this grave malady by operative measures. The symptom chiefly calling for operation was the presence of grave hematemesis. The results quoted are not encouraging, since in a series of twelve operations no less than eight fatalities occurred. The operation adopted is that of gastro-enterostomy, an operation which at first sight seems scarcely calculated to attain the end in view. It is claimed, however, that the operation gives repose to the stomach, and lessens or does away with contraction of the pylorus, two conditions which favorably influence the ulcerative process. M. Hartmann has also adopted the same measure with success in a grave form of dyspepsia, with pyloric spasm,

pain, and vomiting. So far as the spasm is concerned, he holds that it is benefited, whether it may be due to an ulcer, or to hyperchlorhydria, or anachlorhydria. He prefers an anterior gastro-enterostomy, and insists on the importance of fixing the bowel over a large extent of the anterior surface, so as to avoid a spur. It is in addition fixed obliquely from below upwards, and from left to right. He discards any form of anastomotic button. He first of all makes a double suture with silk (*en surget*). The first suturing includes all the tunics of the stomach and intestine, and is hemostatic. The second suture is sero-muscular, and covers the first.

In the discussion which followed, M. Rouzier related the case of a patient whom he had had under observation for a time. The patient was aged forty-five years, and had been the subject of grave dyspeptic troubles for a considerable period, with extreme pain and vomiting. He had thought of both ulceration and cancer in connection with the case, but as the patient continued to live, he found it difficult to conclude what was really the matter. Gastro-enterostomy was finally performed in May, 1897, and singularly enough no observable lesion whatever was detected. The gastro-enterostomy was made posteriorly with Murphy's button. Since then the patient's health has continued excellent, and all his symptoms have quite disappeared.

M. Tuffier raised the question of the diagnosis between ulcer and erosion in cases of grave hemorrhage from the stomach. He considered that clinically it was impossible to differentiate the two conditions. During an operation the ulcer could, of course, be felt, but an erosion would only be seen during an autopsy. He preferred to do the operation posteriorly, as the anterior method involved a risk of too much flexion of the intestine, unless the union was made over a considerable extent. One objection to posterior gastro-enterostomy was that a breach was made at the level of the meso-colon, which might ultimately allow strangulation of intestine to take place. But if care was taken to accurately close the opening that objection was done away with.

---

### PUERPERAL ECLAMPSIA.

On this never-ceasing topic of interest T. G. STEVENS writes in the London *Lancet* of May 14, 1898. After considering the causes, prognosis and autopsy findings in eclamptic cases he proceeds to describe his

plan of treatment. This is based on the assumption of the toxemic theory and may be divided into two categories: first, the treatment of the cause of the disease, and secondly, the treatment of the convulsions themselves. The first, of course, is the more important, and briefly put, consists in aiding Nature as far as possible to eliminate the poisonous toxic principles from the body. The usual avenues for the elimination of excretions are the skin, the kidneys, and the bowels. We can stimulate either of these to increased action, and if the kidneys are inadequate the extra action of the other two may be made to compensate somewhat. To stimulate the skin and to promote diaphoresis we use the hot bath at 100° F., or the hot vapor or air bath, or the hot wet pack. The author need not go into the question of how to use these. He does not believe in drugs to induce sweating, and especially *not* pilocarpine. It is a dangerous drug to use in these cases on account of its depressing action on the heart and the danger of asphyxia from the large amount of bronchial mucus it produces. Drugs by the mouth, of course, are contraindicated because the patient is usually unconscious. As the urine is unusually scanty, and the kidneys are probably deeply congested, active measures must be taken to relieve these. An old-fashioned but very efficacious remedy is dry cupping to the loins, followed by linseed-meal poultices. Infusion of salt water (one drachm to the pint) into the veins or subcutaneous tissue is very useful in promoting diuresis.

In many of these cases the temperature is at very high tension, as shown by plethora and the very hard pulse; this condition by itself greatly embarrasses the action of the kidney (or possibly the inadequate kidney really produces it), and the author is confident that for such a condition there is nothing to compare with bleeding. It acts by relieving the circulation and lowering the tension, by diminishing the congestion of the kidneys, and very probably also by removing some of the toxic principles from the blood. The quantity of blood removed should not exceed twenty ounces. He has twice used bleeding in typical cases, and both times the result was all that could be desired; the pulse became slower and the tension was relieved, and the fits stopped entirely and did not recur. Bleeding must not be employed when the patient is anemic or when the circulation is feeble. The time-honored treatment for

the bowels is to give two minims of croton oil, but the author is bound to say that this does not always have any effect. Any drug which can be given to an unconscious patient and which will produce a liquid motion may be used and will help to relieve the circulation.

With regard to the treatment of the convulsions the patient must be prevented from hurting herself through falling out of bed or biting her tongue. Chloroform must be given by inhalation, and light anesthesia may be continued for hours, increasing the dose if it seems to be coming on. As an alternative to chloroform morphine has been largely used of late years at the Rotunda Hospital, Dublin. It is given hypodermically in full doses until the full effect is reached, and it is claimed that the results have been better since chloroform has been abolished. There need be no fear of giving morphine on account of the renal complication. It does not seem to matter whether the kidneys are sound or not; indeed, morphine is largely given nowadays in chronic Bright's disease. Besides these bromide of potassium is generally given with or without chloral hydrate by the rectum—from thirty to sixty grains of the former and thirty grains of the latter—but very little good could be expected from them alone. His own experience of these drugs is limited to chloroform, but his cases are too few and too uniformly happy in their ending for him to be able to say much about it.

To the author's mind there can be no doubt that labor should be induced where eclampsia precedes. He is convinced that nothing gives the mother a better chance of recovery than a rapid but safe and deliberate delivery. No forced delivery should be attempted, the greatest care must be taken not to produce tears, and above all, the strictest antiseptic precautions must be taken; for a patient recovering from eclampsia is in the worst possible condition for withstanding septic microbes, and therefore is more prone to septicemia than other presumably less worn-out patients. Nothing could be more miserable than to pull a patient through an attack of eclampsia only to see her succumb to the ubiquitous streptococcus. The greatest success in these cases will be with him who carries out all these methods of treatment, not hesitating to pile up one upon the other until the disease is checked.

As a routine treatment for a given case the author would suggest the following: Give chloroform or keep the patient under

morphine and also give the bromides and chloral per rectum. Protect the patient from injury. Induce labor. Bleed if the pulse is hard and the patient is plethoric. Give a hot wet pack or bath. Dry-cup the loins and then put on linseed-meal poultices. Give two minims of croton oil on a bread crumb placed on the tongue. In a large percentage of cases a good result will be obtained if treated in this manner. Even with all this treatment, however, there are, unfortunately, cases which do terminate fatally; but as far as we are concerned, we cannot recognize them beforehand, and so we must not omit one item of the treatment.

---

*THE USE OF IRON AND OPIUM IN  
BRIGHT'S DISEASE.*

In the *Journal of the American Medical Association* of July 23, 1898, TYSON, of Philadelphia, tells us that he has learned since advocating iron in all cases of Bright's disease that there is a good deal of mischief done by iron in this malady, and he is not sure that it would not have been better for many patients if the gallons of Basham's mixture which have been prescribed since Dickinson first suggested it over twenty-five years ago had been poured into the street gutter rather than into the stomachs of the patients it was intended to benefit. It is an interesting fact, confirming the statement already made, that scarcely a patient ever comes to him in consultation or is sent from another physician who has not been taking Basham's mixture, and it is further confirmation that in a very large number of these cases it is given under the impression that it has some specific effect toward curing Bright's disease. It is needless to say that it was never suggested for any directly curative purpose, but simply as a remedy for the anemia which is so conspicuous a symptom in many cases, and for this purpose it still is and always will be useful.

But not every case of Bright's disease is anemic, and as iron has no specific curative effect it is clearly not indicated in non-anemic cases. Nay more, it is often harmful. It is harmful by locking up secretion and checking elimination already restricted by the diminished functional activity of the kidney. The direct results of this are seen in headache and head-throbbing, associated with constipation and coated tongue, to which the patients themselves often call attention, and which appear much earlier in these cases than in persons who have integral kidneys.

In such cases Basham's mixture or iron in any form may even precipitate uremic symptoms.

While anemia as determined by the appearance of the patient and more accurately by a blood count and hemoglobin measurement is the only indication for the use of iron, it is possible also to indicate in a general way the class of cases in which iron may or may not be useful. Thus it may be laid down as a rule to which there is almost no exception that iron is not indicated, and should not be prescribed, in cases of acute Bright's disease. Iron is at best a remedy of slow operation so far as good effect is concerned, while it is rapid in producing its harmful influence, whatever that may be. In acute Bright's disease there is not generally anemia, and where there is it is of secondary importance to more urgent symptoms. It is trespassing on nature, therefore, and embarrassing other more urgent treatment to give iron in acute nephritis. On the other hand, after the acute symptoms have passed away and convalescence sets in iron is often very useful.

A second class of cases in which iron is contraindicated and is more frequently harmful is chronic interstitial nephritis. The association in this condition of more general total destruction of tubular epithelium with restricted elimination goes to show that it is not unlikely that in parenchymatous nephritis, acute and chronic, the renal cells are capable of a certain degree of function even though they be cloudy and swollen. At any rate, it is in chronic interstitial nephritis that iron is more promptly and dangerously harmful than in any other form of Bright's disease. It does happen that in advanced stages of this affection there is sometimes extreme anemia, and it would seem that under these circumstances it might be used; and under such circumstances, if at all, it may be. But even in this, representing as it does the last stages of the disease, in which a dilated heart is staggering under a load it can barely carry and in which a last straw may either cause it to stop beating or furnish the spark to ignite a fatal uremia, the drug is of questionable value.

The form of Bright's disease in which iron is best borne is chronic parenchymatous nephritis; and as this is apt to be associated with more or less anemia it becomes a most valuable remedy in overcoming this symptom. Even here the doses given are usually needlessly large. The writer holds that wherever iron appears in the stools, for what-

ever cause administered, this unabsorbed portion is useless, and as it is this which acting as an astringent causes constipation, it is not only wasted but harmful. His practise is to determine the proper dose by an examination of the stools, and if these are decidedly blackened, he holds that he is giving too much. On the other hand a slight coloration may be permitted as indicating that a sufficient dose has been attained.

A further explanation of the general use of Basham's mixture is the very common impression that this preparation of iron is diuretic. The writer is inclined to believe that this is an error, or at any rate it is no more diuretic than the bulk of water which constitutes its menstruum. That some diuretic action may be expected from this source is rendered reasonable by the fact that Basham's mixture, and in fact any preparation of iron, is commonly freely diluted. The ingestion and absorption of so large a bulk of water may be reasonably expected, by the increased intravascular pressure which it excites, to produce increased secretion of urine.

As to the second of the drugs mentioned in the title of this paper, the writer believes the dangers of its use are more generally appreciated, and yet he is confident that many a life is sacrificed by the injudicious use of opium. He believes, therefore, that a word of warning cannot be out of place. That we should endeavor to understand the conditions contraindicating the use of opium in Bright's disease is the more important, because there are certain states in which opium has been held to be of signal advantage, namely, in the treatment of uremic convulsions. He regards the evidence in favor of the efficiency of hypodermic injections of morphine in certain cases of uremic convulsions as altogether too conclusive to admit of denial, yet he is certain that death has not infrequently been precipitated by it, and when he tells us he has seen a fatal uremia induced by a couple of teaspoonfuls of paregoric, he trusts to convey an adequate idea of the dangers of this drug.

First, perhaps, it is desirable to know the conditions in which opium is positively contraindicated. First and foremost is chronic interstitial nephritis. The writer regards the use of morphine in this form of Bright's disease as harmful in the extreme, and the hypodermic injection of morphine in such cases should be positively forbidden. It is this form of disease in which he has known so many cases launched upon a last sleep

whence they have never awakened. He does not think it possible to be too emphatic on this subject, and he desires to raise his voice against it in the strongest terms. The beginning of the evil result is a diminution and finally a suppression of urine, followed by coma and death. It is especially in old persons in whom chronic interstitial nephritis is unsuspected in which this accident occurs. Hence, too, the importance of examining the urine of old persons before administering opium.

After chronic interstitial nephritis come cases of so-called surgical kidney or suppurating kidney due to stone in the bladder, tuberculosis of the kidney, and the like. The danger in these cases depends a good deal on the degree of kidney substance destroyed. It is well known that operation alone in some of these cases becomes the exciting cause of graver changes which terminate in uremia, as seen in the well known case of the Emperor Napoleon III, while Tyson is confident the use of opium has precipitated many more. Fortunately, the modern practise of surgeons in repudiating almost entirely the use of opium after operation has served to diminish largely the number of accidents from this cause, while another saving clause exists in the fact that while the kidney is often extensively destroyed, in many cases there remain considerable areas in which the kidney substance is sound. This is in marked contrast to the state of affairs in chronic interstitial nephritis, where the invasion is uniform.

Finally, the more extensive the destruction of the kidney, whatever the form of the disease, the greater the danger from the use of opium. Therefore, chronicity becomes in a general way a measure of the danger risked. The writer says, to some extent, because the progress in different cases varies so much, that duration is not always a measure of the destruction of the kidney. On this account chronicity has its limitations as a sign of danger when we have not chronic interstitial nephritis. On the other hand, it becomes more important to insist on great caution in the use of opium in every case of renal disease. In chronic cases of the more doubtful kind the way may be felt by means of very small doses gradually increased, where opium is indicated for any cause.

A corollary following from the last rule brings us to those cases in which the use of opium is least harmful and in many conditions most happy in its influences. These are cases of acute nephritis and of puerperal

nephritis, and the condition in which it is often useful is the uremic convulsion in such cases. The use of opium in the treatment of uremic convulsions in acute Bright's disease is intimately associated with the name of Alfred Loomis, and his original position has been much misrepresented. It was only in acute Bright's disease, as Dr. Loomis himself told the author, that he recommended hypodermic injections of morphine, while others claiming to follow him have advised it for convulsions in all stages. The writer believes Dr. Loomis' original position is justified and that we may still use with signal advantage this mode of treatment. The only risk lies in cases in which the diagnosis is doubtful, and the treatment should not be applied without careful investigation—indeed, dispensed with except in cases of absolute certainty.

The treatment of puerperal convulsions by the hypodermic injection of morphine is justified on the ground that most of these patients represent cases of acute nephritis. But here, even more than in the cases just described, great caution should be used, for not every case of puerperal convulsions is a case of acute Bright's disease, and now and then it happens that death is precipitated because such a case happens in which the use of opium is dangerous.

It will appear from what has been said that diagnosis is the safety gauge by which danger is to be averted. First of all, we should be certain that cases of other disease requiring the use of morphine are not complicated with chronic Bright's disease. Cases in which the writer has known accident to happen have been simple diarrhea calling for the use of opium, and violently painful conditions, such as angina pectoris. In no symptom of Bright's disease itself can opium be of use except in convulsions, and for this symptom only in cases of acute nephritis, whether originating from the ordinary causes or pregnancy, and so rarely in chronic parenchymatous nephritis that it may be practically ignored. Finally, under no circumstances in chronic interstitial nephritis should opium be used.

#### POST-PARTUM HEMORRHAGE.

J. V. HENNESSEY writes in the *Albany Medical Annals* for July, 1898, on this important subject. He believes that the causes predisposing to excessive hemorrhage are general or local. The general causes are usually the result of a morbid blood state,

as in nephritis, diabetes, etc. The local causes are generally due to the condition of the uterus, as overdistention from multiple pregnancy, hydramnios, etc., also short or entangled cord, with resulting traction on the placenta, and precipitant labor.

Etherization of the patient seems to act as a cause, whether because of the anesthetic or because it is most often used in abnormal or instrumental labors the writer does not know, but certainly he has seen severe hemorrhage following its use in an undue proportion of cases. When any of these predisposing causes are operative, they may be recognized, and to an extent guarded against. There is one symptom, however, often unconnected with any of the predisposing causes mentioned, the presence of which always warns him of the probability of serious hemorrhage either before or after the expulsion of the placenta, and that is a marked irregularity in the rhythm or force of the uterine contractions.

The writer believes the irregularity of contractions is due to partial and often very slight separation of the placenta, as he has observed in some of these cases a firm and adherent clot of blood on the margin of the placenta. In these cases the loss of blood is greatest before the expulsion of the placenta, as a rule, and the treatment should be prompt, and if necessary vigorous, to induce its removal. This is generally not a difficult matter, but he recalls a case within the last year in which he had to care for a most unruly patient, with an hour-glass contraction of the uterus, retaining a partially separated placenta, with excessive hemorrhage. In this case the treatment consisted of passing the hand into the vagina, forming a cone of the fingers and thumb, and making a strong and steady counter-pressure over the fundus. The cone or wedge gradually overcame the contraction and removal was effected.

The treatment of hemorrhage after the expulsion of the placenta may be summarized as the administration of ergot by the mouth or hypodermically; the intra-uterine injection of hot water, vinegar, or some other styptic; the placing of pieces of ice in the uterine cavity; the removal of blood-clots from the uterus by the hand. The value of ergot is undoubtedly great when administered in the latter part of the second stage of labor, after it has had time to be absorbed, in producing and continuing firm uterine contractions. But in the face of a present and severe post-partum hemorrhage the writer

hardly thinks that it would pay for the time lost in administering it. The injection of hot water or of vinegar is no doubt of value, but either takes time, which he believes might be much better employed. The one means upon which he has long relied is the manual and rapid removal of retained blood-clots. Since he first realized the importance of this procedure he has lost the dread of this complication. It is to the method of doing this and to what may be observed in its performance that he particularly desires to call attention.

Sometimes the uterus is flaccid and does not contract firmly, and in such cases the clots may be large and soft. More often, however, there seems to be moderately or even decidedly firm contraction. The organ is firm and small, and may be grasped in the hand, while at the same time the blood pours from the vagina. If now the uterus be firmly held in one hand and the other passed into the vagina (this is easily and quickly done after the passage of the child), the index and middle fingers enter the uterus, which at the same time is steadily crowded down by pressure on the fundus. The fingers then discover, not clots of any size, but a velvety feeling, as they sweep around the cavity. Now if a vigorous scraping by the ends of the fingers, not the nails, includes every portion of the under surface of the uterus, and particularly the higher part of the fundus, where at this time the cavity is small and wedge-shaped, the velvety feeling will disappear, and the firm, muscular wall of this organ will be distinguished.

If the hand is now withdrawn, a few small, firm shreds of blood-clot will probably be brought out on the fingers. They may not in bulk be much larger than a white bean, and would easily escape notice unless looked for. Thus far the writer has yet to see a case in which the bleeding was not instantly checked, and it did not return after this treatment. If owing to a morbid blood state hemorrhage should still continue, he believes that a piece of gauze saturated with a styptic solution (vinegar being probably the best) passed into the uterus and left there for an hour would be the most promising treatment. [The objection to vinegar is that it is not aseptic.—Ed.]

In every work on obstetrics great stress is rightly placed on the necessity for the removal of blood-clots in post-partum hemorrhage, but Hennessey does not believe that the important part that the small shreds assume in contributing to a localized atony

of the uterus and consequent loss of blood is very generally appreciated. The stimulus to firm uterine contraction produced by the grasping hand outside and the scraping fingers within no doubt is considerable, but as severe bleeding often takes place from what appears to be a firmly contracted uterus, the writer feels that the small shreds, spread like a film over the placental site, produce their effect by keeping open the uterine sinuses.

In closing the writer remarks that of all puerperal conditions requiring treatment, it is most essential that this one should be promptly met, and to do this it should be discovered in its very beginning. For this reason, during the first twenty or thirty minutes following labor the hand should be often slipped over the fundus uteri so that any undue enlargement from concealed hemorrhage may be quickly recognized. This, with some watchfulness of the pulse and of the discharge, will be a sufficient guard.

#### TEMPORARY RELIEF OF TOOTHACHE.

Under this heading we are told by ACKLAND in *Treatment* of June 23, 1898, to treat toothache in the following manner:

First syringe and well wash out the cavity or cavities with a solution of carbolic acid in water (one in forty) to remove the mechanical or chemical irritants as far as possible. Now take two pieces of cotton-wool and prepare them as follows: The first, a mere shred, soak in carbolic and water, one in twenty; the second, and larger—of a size so as to nearly fill the cavity when slightly compressed—soak in ordinary surgical collodion. Then dry out the cavity with a piece of cotton-wool, using an ordinary pair of dressing forceps, and immediately insert the shred of cotton-wool wet with the carbolic solution, followed as quickly by the large pellet of collodion wool. Should the shape of the cavity be against its retaining this temporary stopping, try to use a surface of an adjoining tooth to help to keep it in. The collodion precipitates in the meshes of the cotton, and will soon form a temporary stopping, which, although not of course preventing further decay, will generally tide the patient over for a time, without further pain. If there be more than one sensitive cavity, put a temporary stopping in each.

Inflammation of the peridental membrane and periosteum is generally a result of the death of the tooth following on the further

development of a foregoing pulpitis. It is generally very easy to diagnose, as the slightest pressure on the affected tooth causes pain, and tenderness on the gum over the root or roots is always present. In the mild form it is best treated by drying the gum and painting on a liniment made up as follows:

Liniment iodi,  
Tinct. aconiti, of each 1 minim;  
Chloroformi, 10 minims.

In this form it is sometimes associated with pulpitis, in which case treat the pulp first and paint on the liniment after. In a later stage, but before suppuration has taken place, inject into the periosteum three or four minims of a one-per-cent. solution of cocaine, freshly made with distilled water, or, failing cocaine, use distilled water only. Hold the point of the needle obliquely against the side of the tooth so as to guide it into the interval between the root and the alveolar bone. In the suppurative and abscess stages poppy-head fomentations held hot in the mouth is generally the most effective treatment. They are best made by taking two ounces of poppy-heads and boiling them in a pint of water sufficiently to evaporate to half a pint in volume, straining off the liquid, and using it hot. Leeches, with or without a tube, can be applied if the patient will undergo the treatment. If an abscess be present it should be drained if possible.

A great deal of relief is often given by general treatment, such as the use of calomel and mild purges.

#### ON THE USE OF THE *SENECIOS* IN FUNCTIONAL AMENORRHEA.

An exhaustive and valuable paper on this topic has just been printed in the *Edinburgh Medical Journal* for May, 1898. As the result of a long series of experiments the writer is led to agree with Murrell that "senecio is not an ecbolic." He also agrees with Murrell that the drug will not provoke menstruation in cases of marked anemia or advanced phthisis, but will do so in cases of functional amenorrhea. Murrell, however, judged that senecio increases the quantity of the discharge, while his own cases point to the opposite conclusion. The views of Bardet and Bolognesi are identical with the author's on these points, though they differ as to the mode of action of the drug. As to dysmenorrhea, Murrell and Dalché and Heim found the drug useful in certain cases, while he is inclined to agree with Bardet and

Bolognesi that it will not be found of much advantage for the relief of pain.

A little thought on the physiology of menstruation will provide a working hypothesis for the action of senecio which is sufficiently reasonable to justify its use, and which also defines its indications.

A man, while his weight remains constant, elaborates from his food an amount of highly organized material exactly equal to the amount of similar material broken down by his activity and removed from his body by lungs, kidneys, and skin. Income and expenditure of protoplasm in the adult healthy male are equal—the anabolic changes balance the catabolic.

A woman, on the other hand, manufactures during her reproductive life highly organized material in a quantity larger than that needed for her individual use. Her protoplasmic income is greater than her protoplasmic expenditure from puberty to the menopause—her anabolic changes preponderate over the catabolic, and the balance is expressed as follows: During pregnancy the anabolic surplus goes to form the fetus; during lactation it supplies the milk; at other times it is lost at monthly intervals by hemorrhage from the uterine mucosa. Before puberty and after the menopause, though female in structure woman is not reproductive in function; and the balance between the anabolic and catabolic changes that together constitute her metabolism is disturbed, as in man, only when weight is being gained or lost. Thus we can see the physiological significance of a periodic sanguineous discharge from the uterine mucosa. With the evolution of the function we are not here concerned, nor yet with the adaptation of the human ovum for implantation on a surface denuded of its epithelium by menstruation. It is necessary, however, to know what determines the particular time at which menstruation shall occur.

Congestion of the reproductive organs accompanying the rupture of an ovisac has, until recently, been thought to be the immediate cause of each menstrual flow. But we now know that ovulation can occur without menstruation, and that menstruation can go on without ovulation. The proofs of these statements are too well known to need recapitulation, but two cases described by Bossi may be mentioned. In one there was monthly bleeding from the anus in a patient who had no vagina, and in whom both ovaries and uterus were infantile. In the other case, a

woman aged thirty-seven, who had always menstruated regularly, became affected with too prolonged periods, during which the discharge was unduly large in amount. Hysterectomy was performed and it was found that she had no ovaries nor tubes! The fact that the removal of both ovaries and tubes does not always cause cessation of the menstrual function points to the conclusion that when Battey's or Tait's operation does cause a premature menopause, it is not through the removal of the organs, but by the division of certain nerves in the broad ligaments. This view has led to the formulation of the "nervous theory" of menstruation; and we now agree with Christopher Martin that the function is presided over by a special center situated in the lumbar part of the cord, and that impulses to menstruate reach the uterus through the pelvic splanchnics or the ovarian plexus, or by both routes.

Thus menstruation expresses an anabolic surplus produced by the healthy human female from puberty to the menopause, its occurrence being determined as to time by the activity of a special center. In the light of this view of menstruation, we see that substances like iron, which affect the quality or quantity of the blood, are only indirectly emmenagogues. Substances which, by causing renal or gastro intestinal irritation, promote pelvic congestion and uterine hemorrhage should hardly be called emmenagogues at all. A true direct emmenagogue must act on the nervous mechanism which initiates menstruation, and this appears to be the mode of action of senecio.

Having thus cleared our ideas, we can now classify the commoner kinds of amenorrhea in a way which shows which cases are suitable for direct treatment by an emmenagogue such as senecio.

Amenorrhea due to congenital or acquired deficiency or absence of essential reproductive organs—no treatment.

Amenorrhea due to local defects, such as atresia vaginæ, atresia cervicis (congenital or acquired), neoplasms, etc.—surgical and other local treatment.

Amenorrhea due to general disease, which so disturbs metabolism that the patient has no blood to spare, e.g., anemia, phthisis—treatment by drugs and food, acting indirectly.

Functional amenorrhea, due to want of activity of the nervous mechanism initiating menstruation; this includes cases in which the function has never been established, but

where there is no general or local defect sufficient to account for its absence; also cases in which menstruation is arrested by mental or physical shock, hope or fear of pregnancy, and other causes—treatment by a direct emmenagogue, such as senecio.

Several species of the genus *Senecio* which have been specially investigated are as follows:

*Senecio vulgaris* and *S. Jacobæ*: Two alkaloids, senecine and senecionine, in small quantities.

*Senecio aureus*: Used in America.

*Senecio maritimus*: Used in France.

*Senecio canicida*, Mexico: Fatty acid, poisonous.

*Senecio Kämpferi*, Java: Fatty acid (Shimoyana).

*Senecio hieracifolius*, United States: Resin and essential oil.

*Senecio erucifolius*: Alkaloids both present in some quantity.

*Senecio paludosus*: Alkaloids in still greater quantity.

*Senecio gracilis*: Known to herbalists.

Shimoyana found a new fatty acid in *Senecio Kämpferi*, a Javanese species. It was named senecic acid ( $C_8H_8O_3$ ), but is not necessarily identical with the fatty acid of the same name found in *Senecio canicida*, a Mexican poisonous species. This latter is a colorless volatile liquid, whose salts are soluble in water; twenty centigrammes will kill a small dog in four to six hours. A phase of excitement is followed by a phase of depression; then convulsions occur—first clonic, later tetanic; finally, the reflexes are suppressed, and heart and respiration are arrested (Guillouet and Toussaint). In spite of the convulsive action of its acid, *Senecio canicida* has been recommended in epilepsy by Mexican physicians.

Senecin is the brown resinous substance derived from *Senecio Jacobæ* and other species. It was used by Murrell, and was believed by him to contain an active principle of the plant. It is probably a mixture. A resin and an essential oil have been obtained from *Senecio hieracifolius* (Syn. *Erechtites*), a species found in the United States (Todd and Lloyd).

Senecionine ( $C_{18}H_{28}N_2O_6$ ) and senecine are two alkaloids isolated by Grandval and Lajoux. They are bitter bodies, whose salts are soluble in water, and are found in very small quantities in *Senecio vulgaris* and *Senecio Jacobæ*, but in slightly larger proportion in *Senecio erucifolius* and *Senecio paludosus*.

The alkaloids exist only in the subterranean parts of the plants. As the difficulty of obtaining them in any quantity has hitherto prevented their use for clinical experiments, Dalché and Heim propose making separate liquid extracts of the aerial and of the subterranean portions of the plants, experiments which will decide whether the emmenagogue action is due to the alkaloids or to some other active principle. But if Lutz is correct in stating that the alkaloids are found in the root alone, the emmenagogue action cannot be due to them; for the author's liquid extract, which is certainly active, is made from the aerial portion of the plant alone, and therefore should not contain alkaloids. The writer therefore thinks with Murrell that the resinous "senecin" contains the emmenagogue principle.

Wiet found by experiment on frogs and guinea-pigs that chlorohydrate of senecionine destroys the excitability of motor nerves, but leaves intact the irritability of muscle itself. In sufficiently large dose it is a curariform poison. Its effect on sensory nerves remains doubtful. It slows the action of the heart, and in fatal doses stops the organ in systole.

#### *RHEUMATIC PERICARDITIS AND ITS TREATMENT.*

In *La Presse Médicale* of June 4, 1898, is an article by PLICQUE upon this subject. After pointing out that rheumatic pericarditis is in the adult more rare than endocarditis, but in children that rheumatic pericarditis is the more common lesion of the two, and after describing the symptoms of this disease, the chief one of which is perhaps violent pain, he goes on to point out that signs of cardiac collapse, syncope, small pulse and cyanosis may be present. In some of these instances the pericarditis is complicated by a true myocarditis. The treatment is first prophylactic. There is no doubt in Plicque's mind that while the salicylates do much towards relieving the articular pain, they are of little value in preventing cardiac complications, except in that they shorten the duration of the disease. Small doses of sulphate of quinine may also be valuable as a supportant and prophylactic treatment. After the pericarditis has once been established the chief part of the treatment should consist in local counter-irritation. Leeches may be applied over the precordium or wet cups may be used, and this method of treatment often relieves the dyspnea and precordial pain. In some in-

stances the ice-bag, which has been highly recommended by some clinicians, is not well borne, and in its place local applications of mercury and belladonna ointment placed upon flannel may be made. After the acute stage of the pericarditis is past a blister or a cautery may be useful. For the cardiac feebleness small doses of digitalis are advisable, but should these doses produce great slowness of the pulse then tonic treatment consisting in the administration of alcoholic beverages such as champagne, coffee and acetate of ammonium may aid the digitalis. Subcutaneous injections of ether, caffeine, camphorated oil and inhalations of oxygen are also advisable. The necessity for paracentesis in pericarditis rarely arises, but if it does the fifth interspace to the left of the sternum is the best point for inserting the needle.

#### *THE TREATMENT OF ACUTE PERITONEAL TUBERCULOSIS.*

At a recent meeting of the Paris Society of Surgery, LEJARS reported two cases of peritoneal tuberculosis of recent origin and rapid progress, one of which simulated intestinal obstruction, the other acute peritonitis due to perforative appendicitis. In both instances the condition of the patient was most grave when Lejars practised laparotomy. On opening the belly it was found that no strangulation existed, but that the peritoneum was covered with tubercular granulations. After washing the abdominal cavity with artificial serum the abdomen was closed. The acute symptoms disappeared and the general and local disorder was ameliorated, and he believes that the operation has resulted in both a temporary and permanent cure of the case.—*Journal des Praticiens*, June 18, 1898.

#### *ARREST OF HEMORRHAGE FROM LARGE VESSELS BY SUTURING.*

LINDNER (*Berliner Klinik*, April, 1898) reports a case in which, during an attempt to close a fecal fistula in the left groin, the common femoral artery and vein were both opened. The bleeding from the vein was arrested by resection of about three-quarters of an inch of the wounded vessel and by double ligature. The arterial wound, on the other hand, was closed by two rows of fine silk sutures. The patient, an old and feeble man, made a good recovery.

The author remarks that, whilst occlusion

by ligature of a large arterial trunk alone, or of the accompanying venous trunk alone, is not likely to be followed by gangrene of the distal parts, simultaneous ligature of both vessels is, in this respect, attended with much risk, which is more likely to occur after wounds of both common femoral vessels than after a similar injury either of the axillary vessels or of the large vessels of the neck. Experiments on animals and the successful results of cases recorded by Schede have proved that under modern conditions of practical surgery a wounded vein may be sutured effectually without any risk of phlebitis. The indications for suturing are much more urgent in the case of a wound of a large artery, for, however small the wound may be, the prospects of closing it by compression are not so favorable as in the case of even a large venous wound. The practise of suturing an arterial wound must be subject to certain restrictions, as experience has proved that it would not be safe to apply a suture to a transverse wound involving more than one-half the circumference of the vessel. In such cases it would be advisable to resort to the practise advocated by Murphy of resecting the injured portion of the artery and bringing the ends together, the proximal end being invaginated into the distal one, and fixing them by five sutures. In practising arterial suture Lindner would transfix all the coats of the vessel, and in selecting the material of his suture would prefer fine silk to catgut. —*British Medical Journal*, June 11, 1898.

#### THE ANAPHRODISIAC ACTION OF THYROIDIN.

Anaphrodisiacs are not greatly in demand in therapeutics, though various drugs are known to exert incidentally a depressing effect on the genital functions. According to Dr. Riviere, of Lyons, thyroidin is one of the latter group, and he reports two typical cases of men who sought relief from exaggerated obesity in the thyroid treatment. They both lost weight very rapidly under the influence of the drug, but observed with surprise, not unmixed with apprehension, that the sexual function had fallen completely into abeyance. This condition persisted for some time after the cessation of the treatment, though the function was eventually restored. It is suggested that this "therapeutical castration" may possibly help to explain the inhibitory influence ex-

erted by the gland on the growth of uterine myomata and especially on the hemorrhage which their presence occasions. On the same lines there is reason to believe that thyroidin may prove useful in the treatment of prostatic patients whose troubles are due to congestion of the genito-urinary apparatus. — *Medical Press and Circular*, June 1, 1898.

#### THE VALUE OF CERTAIN DRUGS IN THE TREATMENT OF GOUT.

In *The Lancet* of June 11, 1898, LUFF, the authority on gout, concludes that the ordinary alkalies, the lithium salts, piperazine, and lysidine, do not exercise any special solvent effect on sodium biurate, and their administration to gouty subjects with the object of removing uratic deposits in the joints and tissues appears to be useless.

Sodium salicylate does not exercise any special solvent effect on sodium biurate. Its administration with the object of removing uratic deposits in the joints and tissues appears to be useless, and, moreover, it is apparently contraindicated in gout on account of its leading to an increased formation of uric acid in the kidneys.

#### THE TREATMENT OF UREMIC CONVULSIONS AND COMA, WITH SPECIAL REFERENCE TO THE SENILE KIDNEY.

In a recent issue of *The Lancet* WILKINSON, in writing upon uremia, has much of practical use to say of its treatment. He thinks that the prevention and treatment of uremia in senile kidney and other renal failures may be best considered under two heads: (1) attention to diet, and (2) measures calculated to aid excretion, to lower arterial tension, and to quiet convulsions. Though of the greatest importance, a few passing remarks must suffice for the former. Temperate living in old age would lengthen many a life, warding off apoplexy and uremia. Indeed, the marked difference in personal comfort and vivacity brought about by a change in table habits has often astonished both the patients and their friends, as the former entirely ceased to discuss whether life was worth living. This need not entail the adoption of liquid or invalid diet, for in advanced life the stomach usually secretes and digests more satisfactorily when stimulated by solid food than when treated to "slops." The sum total of food should be restricted within

reasonable limits. This is more important than any specific act of self-denial. If an egg or fish be allowed for breakfast animal food should be permitted at one subsequent meal only, and that not too late in the day. To prevent undue condensation of urine the amount of liquid imbibed should average forty fluidounces and be taken chiefly between meals, lest it dilute the gastric juice. Intoxicating liquors are better forbidden; if insisted on, a small amount of diluted dry spirit during the chief meal and at bedtime may open the tardy stomach arterioles and favor sleep. That vascular tension is thus kept down is matter of observation. Prolonged uremic coma, just like an attack of gout, is a time of diminished ingestion, and the latter no doubt aids the recovery.

Under the second head the author discusses in more detail the value of (a) purgatives; (b) chloroform, bleeding, and the nitrites; and (c) diaphoretics. The importance of attention to the bowels cannot be overestimated. Not only does regularity greatly lessen the chances of secondary fermentations and toxin formation, but by purgation we can turn out of the body bile and half-digested food and also command the radicles of that vein which carries the crude products of digestion to the great provident dispensary of the body, the liver, where for weal or woe so many mixtures are made. Modern abdominal surgeons, whose one aim in the old days was to keep the intestines quiet, are now beginning to realize their value in elimination and to substitute calomel and salines for opium. They talk of "the race for the bowels," and use the intestine as if it were a drainage tube.

The writer firmly believes that in commanding the liver and intestines we hold the most important excretory area in the body after the kidneys. In this respect the views of the late Dr. Mahomed were undoubtedly correct. Indeed, the efficacy of purgation in high arterial tension and uremia is acknowledged by all, but there is still considerable diversity of opinion as to the relative value of the different drugs. May we employ calomel? Sir William Broadbent places it *facile princeps* amongst the drugs which lower arterial tension and strongly advocates its use in from two- to five-grain doses. Many other writers—*e.g.*, Dr. Whitla in his excellent Dictionary of Treatment—only mention it in order to warn their readers not to prescribe it, and the writer's early training and teaching ran in the same

groove. Now he frequently exhibits it when he has reason to regard the uremic phenomena as out of proportion to the organic renal change. Should the cells of the kidney be much degenerated—that is to say, in parenchymatous disease with dropsy, marked albuminuria, and abundant fatty epithelium and casts—the drug is distinctly dangerous. Quite recently he saw such a case in which five grains of calomel had been given. It stopped the uremic vomiting, relieved for the time the headache, and lowered the blood tension, but the marked swelling and tenderness of the salivary glands and gums, the furred, foul tongue, etc., gave ample evidence that the administration was a mistake.

In the terminal uremia of Bright's disease calomel acts as a poison, and the more definitely the cerebral phenomena depend on organic renal failure the more doubtful the use of mercury. The condition of the kidneys in Bright's disease is in the writer's opinion to be our guide. It is the fact that severe convulsions and coma may be associated with a minimal or passing renal defect that makes calomel admissible. That all such cases have exactly the same pathological substratum the writer is far from believing, but the use of calomel is not limited to those conditions in which the renal trouble is only transitory. Whenever the blood tension is high, the urine is passed in fair quantity, of average or high specific gravity, deposits urates and contains only a small amount of albumen, he employs calomel without hesitation. Taken alone the amount of albumen present is of little importance. In puerperal convulsions he has seen very highly albuminous urine return to the normal within a few hours. Numerous and varied renal casts must, however, make us pause, more especially if they testify to chronic tubal change.

In senile failure, and in the middle and later stages of chronic interstitial nephritis, we must remember that the system is sensitive to mercury and therefore recall Dr. Ringer's remarks on minimal dosage. In early days the writer saw thirteen grains and twenty grains of calomel given as a purge with excellent results. The Cheadle bulldogs, of local repute, are said to owe their ferocity to this drug. Such treatment in renal failure could only be regarded as tempting Providence. One grain is often an ample dose. Quite recently the author saw a gentleman, well in the "teens" of stones, who smiled at the powder in the evening, but

assured the writer that his respect for it was considerably raised on the following morning, as it kept him from business. A lady, aged seventy-six years, who was under his observation for several years with gouty cardio-arterial and retinal changes, was severely purged by one grain of calomel, but so greatly relieved thereby that for three or four weeks after each dose she seemed to have taken a new lease of life. The same lady for three years took five grains or more of pulvis ipecacuanhæ compositus every night with great advantage, a method of administering opium in Bright's disease which the author considers to be safer than any other. As commonly happens, this patient died from an acute and entirely independent affection.

Calomel undoubtedly reduces high arterial tension and relieves the troublesome cardiac, pulmonary and cerebral phenomena associated with it. It takes several hours to act, but the effect produced is less evanescent than with other drugs. How calomel acts the writer does not profess to explain. That mercurials will often clear a dense uratic urine is known to all. Elimination of bile by the bowel is probably the principal part of the programme. Anyhow, in dealing with high tension calomel is superior to all other purgatives, including blue pill. It sweeps and drains the intestines as well as the hepatic ducts, and in his opinion differs materially from crude mercury in its action. In a case of obstructive jaundice of some weeks' standing, now under the writer's care in the Manchester Royal Infirmary, in which the administration of olive oil, massage and other treatment have failed to remove the obstruction, both patient and medical man gave independent witness that one grain of blue pill taken three times a day increased the color of the skin and urine, while one-grain doses of calomel caused decided improvement in the digestion and complexion and lessened the urinary excretion of bile, in spite of the continuance of the block in the main duct.

Next to calomel, but as its aide-de-camp rather than its substitute, the author does not hesitate to place Epsom salts, and in acute cases he is accustomed to follow up the calomel after five or six hours with two- to four-drachm doses till free purgation occurs. In chronic high tension an aperient dose of the *mistura alba* on rising each morning gives very definite relief. He uses it extensively in out-patient practice and finds, as Dr. Whitla observes, that it can be continued with advantage for long periods. Our mer-

curial ancestors, with their nightly blue pill and morning black draught, and their by no means delicate attentions to the *primæ viæ*, were perhaps nearer the mark than some of the more scientific moderns. The writer is told that a friend of his, a clergyman, was a younger and a better man whenever he had time and grace to attend to his bowels. When calomel is contraindicated, and especially if dropsy be present, he often employs the compound jalap powder in drachm doses. Some fortify it with elaterium; but Wilkinson's experience of the latter drug has not been encouraging. On two occasions the fault may have been in the quality of the drug supplied; in other cases it has been rejected or failed to act. An extra drachm or two of bitartrate of potash may be added, as recommended by Sir William Roberts, with excellent result.

There are, however, cases in which the convulsions are so severe and the whole condition so critical that some method of treatment more rapid than purgation is urgently demanded. If the blood tension be high, Wilkinson believes that both theory and practise uphold blood-letting as a reasonable and efficient remedy. It is true that physiology teaches us that moderate venesection does not lower the arterial blood-pressure, and arguments have been based on this statement deriding its utility in disease. But surely a deviation from the normal is a very different thing from a return to the normal. The aim of the automatic regulating mechanism of the body is to secure normality. It may raise the blood-pressure with a view to increased excretion, but it will gladly allow a return to the normal if practicable.

The writer advocates bleeding as a temporary device to tide over a crisis; that it accomplishes its end is undoubted. It must in most cases be backed up by measures more definitely depurative in character, dietetic and excretory. Some obstetric writers, like Dr. Galabin, absolutely set their faces against it. A friend of the writer's, surgeon to a large hospital, who has had a wide experience in such cases, told him that the only patient he lost in puerperal convulsions was the only one he did not bleed. Its utility in uremia is maintained by such authorities as Sir William Roberts, Sir William Broadbent, and Dr. Osler. It may be employed with advantage in all cases in which calomel is admissible. Where the patient is already very anemic and the kidneys are far advanced in organic disease, both remedies are

worse than useless and the prognosis is not markedly affected by any treatment. In the clergyman first referred to the congested face and full habit of body distinctly warranted the use of the lancet, but the absence of convulsions allowed time for the action of still better remedies.

In dealing with severe puerperal eclampsia chloroform by the lungs and chloral and bromide per rectum are of unquestionable value. Nevertheless, though they mitigate the convulsions, like morphine they mask the coma, and the writer is bound to confess that when the pulse tension is high and the patient is plethoric he is inclined to the older method of treatment. Of the reputed value of morphine in uremia proper he has had no experience and prefers to commence the trial of it on his enemies rather than on his friends. Still it is peculiar that the two drugs, mercury and opium, against the use of which in Bright's disease we were formerly warned, should be now both to the front in the treatment of uremia. This does not prove that the former fears were groundless, but rather supports the writer's present position, namely, that the more pronounced symptoms of uremia, coma and convulsions, are often associated with comparative renal integrity.

In dealing with the results of chronic high tension, the writer has found the nitrites very useful, but so far has not tried them in actual convulsions. An aching head or a heart struggling irregularly and painfully against an overfull arterial system will at once gratefully acknowledge the receipt of a dose of nitrite of ethyl, as suggested by Dr. Leech, or more slowly respond to tabellæ of nitroglycerin. The latter preparation, because of its stability and ease of administration, he frequently employs in chronic high tension. It gave great relief to the second case and may be used to diminish the intense headache which often accompanies the development of albuminuric retinitis. The sphygmograph readily reveals the action of the drug and may be employed to indicate the amount and frequency of the dose required to mitigate the tension. The writer uses the term "mitigate" advisedly, for to relieve the symptoms it is not necessary, nor indeed is it an easy matter, to establish a normal tension. A tabella every six or eight hours is usually sufficient to accomplish the desired end. In one case of cardiac asthma with very irregular high-tension pulse the relief given by the nitrites was so great that the pa-

tient was immediately transferred from his bed to the local races, and the latter end of that man was worse than the first. As his medical attendant observed, the treatment both cured and killed him. Sometimes the nitrites produce definite diuresis, but even this should not lead us to set aside other eliminatory measures. When the kidneys fail the skin presents a large and active secretory area second only in importance to the mucous membrane and glands of the alimentary tract. The fact that in Bright's disease urea is excreted by the skin is a definite indication to the therapist. Of every-day drugs the sweet spirit of nitre and the acetate of ammonia are the most popular and valuable diaphoretics, but in uremia we are compelled to adopt more active measures, such as the external application of heat, wet or dry, and the hypodermic injection of pilocarpine. The hot pack is one of our most valuable remedies and available in almost all cases. It is, however, to be specially selected when calomel and venesection are out of the question, when the system generally, and the connective tissues in particular, are drowned in ureated liquid, and when the brain disturbance is more dependent on direct intoxication than irregularities of arterial pressure; in other words, in the dropsical uremias of blocked or bankrupt kidneys.

The employment of pilocarpine hypodermically is not without its dangers. Nevertheless, if other remedies fail, it may be tried, provided the patient possesses full power of deglutition and the thoracic organs are in good condition. Its action should be assisted by the use of hot blankets, or bottles, and warm drinks. Usually the response of the skin is rapid, a few minutes sufficing to start the perspiration, but the response of the system is somewhat more uncertain in time and degree. The effect produced, however, in some cases, as in the second already referred to, is very striking. Personally, the writer avoids the use of the drug if possible, but confesses that he has not tried the method of inunction recommended in milder cases by some writers with the object of reducing the risk of cardiac collapse and pulmonary edema to a minimum. As pilocarpine is recommended in some forms of insanity it may be interesting to add that the writer's friend, Dr. Wansbrough Jones, after the hypodermic injection of one-third grain for ocular disease, witnessed the immediate development of acute melancholia with attempted suicide, and the repetition of the dose some time

later at the recommendation of the oculist led to a similar disturbance followed by several months' detention in an asylum. As there was no family history to suggest such a complication the drug was naturally suspected. At any rate the dangers of pilocarpine are sufficiently real to render its use a matter for deliberation.

#### THE TREATMENT OF SUPPURATION BY BICARBONATE OF SODA.

BRUCKER (*Thèse de Bordeaux*) has made a study of a fact observed by himself, namely, the influence of the reaction of the blood in the healing of certain conditions. Bearing in mind that the normal alkalinity of the blood shows important variations according to sex, age, and as to whether the blood is arterial or venous in origin, and the diet to which the patient has been addicted, and that in certain pathological conditions these variations are very marked, so that a reduction in the normal alkalinity is observed in certain cases of febrile reaction due to bacterial intoxication, he has found that certain artificial intoxications can be combated by raising the alkalinity of the blood by the injection of alkaline serum. Going on these grounds, Brucker has principally investigated the influence of alkaline dressings in the treatment of local inflammatory affections, and according to his observations such a dressing, whether moist or dry, very rapidly reduces the inflammation, suppurative or otherwise, and causes rapid healing of wounds. This seems independent of any antiseptic property in the proper sense of the word. The method employed by him is to apply the dressing of absorbent wool on ordinary principles, using merely a two-per-cent. solution of bicarbonate of soda, or in some cases vaselin and bicarbonate (1 in 25), or the soda may be applied directly in the form of a powder. He finds that strong solutions do not act more quickly than a two-per-cent., showing that the chief agent is the alkali, and not any antiseptic principle. The same method may be applied for purulent otitis, etc. — *British Medical Journal*, June 13, 1898.

#### SOME REMARKS UPON A NEW MYDRIATIC.

STEPHENSON says that the claims of ephedrine hydrochloride as an agent for dilating the pupil have been before the profession for several years, but apparently without attract-

ing anything like general attention. The first communication upon the subject was made by a Japanese physician, Kinnosuke Miura, and this was soon followed by papers from the pens of J. Inouye and A. de Vriese. From these contributions, however, it was clear that the dilatation of the pupil induced by ephedrine was of moderate extent only, although it possessed the great practical advantage of passing off rather quickly (in from one to twenty hours). Later it was found that the action of ephedrine could be enhanced by the addition of a trace of homatropine hydrochlorate in the proportion of a hundredth part of the latter to one part of the former substance. This observation has led to the combination of the two medicaments. The new agent, which is known as "mydrin," is a white powder, readily soluble in water. Its physiological action has been reported upon by Groenouw in Germany, by Suker in America, by Cattaneo in Italy, and by Mr. Simeon Snell in England. These various observers find that a ten-per-cent. aqueous solution when dropped into the eye has the power of dilating the pupil moderately within a few minutes, without affecting accommodation in the least. They also agree that the action of the pupil to light is to some extent retained while the eye is under the influence of the drug, the effects of which pass away within from four to six hours. In no instance have they seen any irritation or inflammation result from the application. Groenouw, who experimented on one hundred patients, found that the dilated pupil had an average diameter of 5.6 millimeters. Suker speaks of mydrin as "an ideal mydriatic for diagnostic purposes," and Mr. Snell's experiences appear also to have been equally favorable.

These claims seem too strong to be set on one side without investigation. Accordingly for some time past the author has used a ten-per-cent. watery solution of mydrin for the purpose of dilating the pupil, when he wished to explore all parts of the fundus oculi with the ophthalmoscope or to examine the cornea carefully in order to ascertain the presence or absence of slight changes. Moreover, for the purpose of more exact study he has recently taken twenty patients and noted in each one (a) the near and distant sight, and (b) the diameter of the pupil. A single drop of mydrin solution (ten-per-cent.) was then placed in the conjunctival sac, after which the following points were observed: (a) the time at which the pupils became

dilated; (b) the transverse diameter of the pupils; (c) the near and distant vision; and (d) the time at which mydriasis passed away.

The results obtained in this way may be thus briefly related: The pupil became dilated in a period which varied, according to the individual, from fifteen to sixty-eight minutes, the average of the twenty observations being 29.35 minutes. The mydriasis was found to ensue more speedily if patients kept their eyelids closed after the application had been made. Owing to the fact that the iris did not completely lose its action to light, there was some little difficulty in measuring the size of the dilated pupil, the transverse diameter of which ranged from 5 to 7.5 millimeters, and averaged 6 millimeters. For a similar reason it was not altogether easy to say with precision when mydriasis had passed away. But in no instance did the maximum time (after full dilatation) exceed four hours, while the minimum stood at seventy-five minutes. The average worked out at 184.84 minutes—that is to say, a trifle more than three hours. In no case did sight, either for distant or near objects, show any alteration when the eye was fully under the influence of mydrin, a remark which applies also to the position of the punctum proximum. Lastly, it is practically important to note that the agent set up neither discomfort nor irritation.

As the result of his observations the writer has reached the conclusion that mydrin is capable of doing all that writers have claimed for it—namely, that it causes a moderate dilatation of the pupil without involving the function of accommodation. It cannot but prove, therefore, a valuable agent in the hands, not only of the ophthalmic surgeon, but also of the physician, who must often be desirous of exploring the fundus oculi with a dilated pupil.

#### SURGICAL SHOCK.

In the *Memphis Lancet* for July ESTES tells us that the recognition of the essential anemia of the brain as the constant pathological factor in shock gives the key to the treatment. The endeavor should be primarily to restore the blood to the brain. As this cerebral condition in psychical shock and in concussion has been produced by the inhibitory action through the pneumogastric by a violent irritation of the medulla, the vasomotor system must of necessity also be violently affected, as the medulla is the center of the vasomotor

nerves. After lowering the head and placing the person in a recumbent position to obtain at least a small quantity of blood for the brain, the next indication will be to excite the action of the sympathetic nerves in order to restore the tone to the heart. Of course, the elementary procedures of loosening the clothing, especially about the neck and waist, and taking care to supply fresh air, must always be observed. Sometimes a quick, violent action of the diaphragm will assist in stirring up the splanchnic and the direct cardiac sympathetic filaments. Hence irritation of the nostrils in order to produce deep respirations or sneezing will do good. Hare recommends an abdominal compress for chloroform poisoning. Direct cardiac stimulants (rarely digitalis), at the head of which stands strychnine, are indicated. Heat to the surface should be applied in order to relax the cutaneous vessels, and friction to the extremities for the same purpose.

Of the greatest importance in cases of psychical shock is it to remove the person from the place or locality which may have excited the dangerous mental condition before he recovers consciousness, else a relapse may occur. In cases of serious injuries it is of the greatest importance to take proper measures to prevent and to control the hemorrhage *during psychical shock*, for very little bleeding will occur until this condition is passed. As almost complete anesthesia exists, an Esmarch tourniquet may be applied, vessels tied, or sutures put in without any disturbance or harm to the patient. In this condition, as soon as consciousness begins to return and so-called reaction begins, an anesthetic, if given, will hasten the reaction and thereby restore somewhat the tone and quality of the pulse. The author thinks these cases have given rise to the contradictory observations of various surgeons who report that in their experience an anesthetic frequently improves the strength of the pulse; hence they recommend undertaking an operation "before the patient reacts from shock." This is a very unsafe recommendation, because if the second stage, acute anemia, has already taken place, any operation which involves the further loss of blood is very apt to be fatal. The safer rule is always to wait with any operative procedure which must be attended with even a small loss of blood.

The treatment of acute anemia is the same as the foregoing, with the full appreciation, however, that this condition is in these cases from an *absolute* as well as functional loss of

blood. Energetic measures must therefore be taken to restore some blood to the brain. The limbs should be tightly bandaged from the extremities upward to drive the blood out of them to the head, the head and shoulders lowered, heat applied externally, and large doses of strychnine hypodermically should be employed. The author has used as much as 0.025 ( $\frac{1}{2}$  grain) of the sulphate of strychnine in the course of an hour in these cases, and about 0.1 ( $1\frac{1}{2}$  grains) in twenty-four hours. Caffeine in the form of best black coffee, digitalis, and the aromatic spirits of ammonia he frequently uses. Alcohol, he thinks, does harm rather than good; in late years he has not used it for shock.

Besides the above remedies, a most important indication is to restore fluid to the empty capillaries and veins. Many surgeons use habitually intravenous injections of a normal saline solution, and formerly the author also used it; he was, however, so frequently disappointed in its ultimate action that he has not used this method for some time. He has found far better rectal injections of this hot saline solution. Now it is always a part of his routine practise in cases of shock to use large or frequent rectal injections of this solution. If the patient is in profound shock the quantity injected may be large—as much as two liters—care being taken to use a soft rectal tube and pass it up to the sigmoid flexure, while the patient has his buttocks raised, and then allow the fluid to flow from a douche can or fountain syringe into the colon. In cases of partial or complete consciousness he uses half a liter of the solution, always injected by gravity alone into the rectum, and repeat it in an hour. The transit through the intestinal walls into the blood-vessels is slower, but in his hands much more efficient than intravenous injections.

As soon as the stomach will retain it, as much water as the patient can take should be given by the mouth. A generous fluid diet of a nitrogenous kind should be allowed for twenty-four or forty-eight hours, and then light but frequent feeding of a more solid kind. He thinks major operations should never be attempted, if they can possibly be postponed, during shock. He believes the very good results he has had in cases of extensive acute injuries are due largely to the fact that he has waited until the patient has had time to recuperate somewhat from his acute anemia before operating. In the cases requiring hip-joint amputations for

injuries he waited thirty, forty, and about forty-two hours respectively before operating.

In conclusion, the author begs the readers of his paper will not lose sight of its main purpose, through the distraction of possible differences as to the theories advanced. He has tried to prove that shock which kills is a condition of acute anemia; that this operates through the brain, as an anemia of the brain, in depressing *all* the so-called vital processes; and that the proper treatment of shock is in the first place prophylactic, namely, to prevent hemorrhage before operation and during operation, and secondly, to cure shock by restoring blood to the brain as rapidly as possible, and then stimulate the heart by warmth, by good air, by strychnine, and by a normal saline solution injected into the rectum or veins. If all else is forgotten, we must keep firmly and carefully to the idea that the life of a man is in his blood, and in order to save a man's life we must save his blood.

---

#### THE TREATMENT OF RUPTURED UTERUS BY MEANS OF GAUZE PACKING.

The *Practitioner* for July, 1898, has an article by MAYO ROBSON upon rupture of the uterus, of interest to us all. Although the obstetric practitioner is accustomed to be brought face to face with trying and anxious complications of various kinds, needing great presence of mind and prompt interference, there is no more formidable accident needing a decided line of treatment than that of ruptured uterus. Where the rupture occurs before delivery and the child escapes into the abdomen, nothing but immediate abdominal section can offer any chance of saving the patient, and in such cases interference, to be of any avail, must be prompt, both on account of the hemorrhage and shock.

Unless the skilled help of a surgeon be immediately available—as, for instance, in a town practise—it would be very unwise to wait for skilled help in the hopes of improvement occurring, as not only will the shock increase, but the continued pouring out of blood into the peritoneum may, even within half an hour, render operation hopeless.

The author thinks it is not fully realized how few special instruments are necessary in order to perform hysterectomy under such circumstances. While the surface of the abdomen is being washed and other arrangements made, a skein of silk or thread, a piece

of baby-bottle tubing, a knitting-needle, and the instruments which an obstetrician will always have with him—viz, a needle, a knife, and artery or pressure forceps—can be boiled. At the same time a quantity of water may be boiled for lavage of the abdomen, and several handkerchiefs or napkins, to be used as sponges or dressings, can be boiled either with the instruments or in a separate pan.

The abdomen may then be opened in the middle line, the ruptured uterus dragged forward and surrounded by a piece of elastic tubing, which is to be tied tightly around the pedicle above or below the ovaries, according to the site of the rupture, the ends being secured by means of a silk ligature to prevent the knot slipping; the knitting-needle can then be pushed through the uterus from side to side just above the ligature, and the portion of uterus beyond can be amputated. The fetus and placenta, if free in the peritoneum, can then be extracted through the abdominal incision, and the abdomen thoroughly washed out with a solution of salt and water in the proportion of about a teaspoonful to a pint, at about a temperature of  $105^{\circ}$ , which can be poured from a pitcher by the nurse.

The boiled handkerchiefs will serve to mop out the extra fluid and to remove any clots, but even if a little fluid be left in the peritoneal cavity it will do no harm—probably rather good than harm, as it will be absorbed rapidly by the lymphatics and help to fill the blood-vessels, rendering transfusion unnecessary.

The abdomen may then be closed in the usual way by means of the boiled thread or silk. Thus, if the surgeon and nurse have taken care to thoroughly cleanse their hands, an almost ideally aseptic and safe operation may be done with this scanty preparation.

But there is a class of cases of ruptured uterus where the laceration is in the lower segment of the womb and where the rent occurs during delivery, and is probably only noticed afterward when hemorrhage and increasing shock draw attention to something being abnormal. In such cases there is as a rule more time for consideration, as the shock, though great, may not be immediate, and the hemorrhage may not be so violent as to produce immediate collapse.

A simple vaginal examination may not discover the rupture, as the lower segment of the cervix is not necessarily torn; but if the finger be passed within the patulous os,

the rent in the uterus will be felt and the symptoms explained.

It is a great question whether in many of these cases hysterectomy is the better operation, and in a discussion at the Obstetrical Society of London, 1897, a speaker said that in two cases in which, under similar circumstances, he had seen the operation done the patients had died on the table, and the only ones that recovered were those in which packing with iodoform gauze had been done.

The following case exemplifies the advantages of gauze packing: Last year the author received a telegram from a medical friend, asking him if he could come at once to assist him with a case of uterine hemorrhage following an abortion at the third month, in which some difficulty had been experienced in removing the ovum, and the cervix had been dilated with Barnes's bags. On arrival he found the patient blanched and suffering from shock, though the external bleeding was not sufficient to account for the symptoms. On examination the vagina was found intact, as were also the os and cervix; but on pulling down the cervix by means of vulsellum forceps, and passing the finger through the patulous os, it readily passed through a considerable rent in the uterus, direct into the peritoneal cavity. The abdomen was a little distended, and on pressure being made over the hypogastric region, blood was forced through the rent and escaped through the vagina. With scissors he divided the portion of the cervix between the laceration and the vagina, so as to get thoroughly at the rent; but he found it to extend so far up the uterus that it was impracticable to apply sutures to effectually occlude it. He therefore had the edges of the laceration held apart, and after curetting and washing out the fundus of the uterus, and compressing the abdomen so as to force all the free blood possible out of it, he packed the laceration very thoroughly with long strips of iodoform gauze, several yards being used, the packing filling the pouch of Douglas, the whole of the laceration, and the upper part of the vagina. A firm pad was applied above the pubes and kept in place by means of an abdominal bandage. The packing was changed on the third day, and after that every second day. No further bleeding occurred, and no peritonitis ensued. Recovery was slow but uninterrupted, and the patient is now perfectly well.

This case exemplifies well the hemostatic value of gauze packing in a ruptured uterus,

a means at once simple and safe, and one which is always available even if only used as first aid, but which will often, as in the case referred to, carry the case to a successful issue without further treatment.

A packet of iodoform gauze goes into small compass and should form one of the components of every obstetrical bag, as the author feels sure it does of every surgeon's instrument case. He has found it convenient to carry his iodoform gauze in strips about one inch broad, already cut for use, stored in a convenient celluloid case; this occupies a small compass in his bag, and is always clean and ready in case of need.

#### THE EXERCISE TREATMENT OF LOCOMOTOR ATAXIA.

The treatment of locomotor ataxia by exercises calculated to teach the patient again the coordination of muscles that has been lost by degeneration of the lower sensory neurons has recently attracted considerable attention, and has won for itself the support of many neurologists, among whom may be mentioned Leydon, Jolly, Mendel, Eulenberg, Oppenheim, Gerhardt, and Remak. This method of treatment was first introduced by Frankel and has for its prime object the conversion of the simplest ataxic movement into a normal one.

In a communication to the *Deutsche Medizinische Wochenschrift* of December 17, 1897, Frankel, describes the various exercises for the hands, arms, body, and legs. For exercising the upper extremities the following directions are given: Sit in front of a table, place the hand upon it, then elevate each finger as far as possible; raise the hand slightly, extend, and then flex each finger and thumb as far as possible; do this with the right and then with the left hand. Touch with the end of the thumb each finger-tip separately and accurately; then touch the middle of each phalanx with the tip of the thumb. Sit at the table with a large sheet of paper and a pencil; make a dot at each corner of the paper and one in the center, and draw lines from the corner dots to the center dot, first with the right and then with the left hand. Put ten coins on the paper, pick them up and place them in a single pile, first with the right and then with the left hand.

For the body and legs, sample exercises: Sit in a chair, rise slowly to erect position without help of cane or arms of chair; then

sit down slowly; stand with cane, feet together; advance left foot and return it, then the same with right. Walk slowly ten steps forward and five back with help of canes. Stand without cane, but with feet a little apart and the hands on the hips; in this position stoop down by flexing the knees, and rise slowly. Stand without cane with the feet separated; raise the hands from sides above the head; carry them downward and forward, and try to touch the toes. Walk along a fixed line on the floor by help of cane, placing each foot in turn on the line; then repeat without using the cane. Most of these exercises should be repeated several times, and the movements should be made with the eyes both open and closed.

Owing to disturbance of the sensory paths tabetics have lost the sense of fatigue, so there is some danger in overdoing the treatment. Two things are therefore insisted upon: first, every movement must be done with the greatest possible exactitude, since it is not simply physical exercise that is aimed at so much as training in coordination; and second, the séance should not last more than eight or ten minutes, and no more than two should be allowed a day.

In the preataxic stage the exercise treatment has in a number of cases prevented the development of incoordination. Even in advanced sclerosis remarkable results may be obtained; in a number of instances patients, bedridden for three, four and five years, have been taught to walk without assistance. The improvement may last for years, if the disease is stationary or only slowly progressive. According to Frankel the treatment is absolutely contraindicated in cases of acute or subacute ataxia.

Kalinin (*Vratch*, No. 7, 1897), who has used Frankel's method in five cases of locomotor ataxia, draws the following conclusions: By this treatment the loss of motion can be restored to a satisfactory degree, the gait and locomotion gradually becoming safer and firmer. The sense of locality and that of movement, and the skin sensibility, are but little improved. Romberg's symptom very soon became less pronounced. The duration of treatment should entirely depend upon the prognosis and the degree of motor disturbances present, but in any case it should not be less than a month. No ill effects were observed when the treatment was interrupted at short intervals of two or three weeks, but not longer.

Raichline, who has treated twelve cases

with complete success in eight, concludes that the conditions of success are a long, as opposed to a short, course of treatment, a well nourished condition, good sight necessary for watching the movements accurately, a certain amount of energy and intelligence, not complete loss of sensibility, and the absence of arthropathies.—*University Medical Magazine*, May, 1898.

#### THE REMOVAL OF FOREIGN BODIES FROM THE UPPER AIR-PASSAGES.

In a recent issue of the *Post Graduate* RICE gives directions about this important topic. He describes a patient who said that two hours before he had swallowed a piece of beef bone, and he located it by putting his finger on the right side of the neck lower down than the tonsil, about the level of the hyoid bone. The author thinks that seventy-five per cent. of the foreign bodies that get into the pharynx have passed into the esophagus and stomach by the time the patient has reached the physician. Nevertheless, just as diligent search should be made to locate them. A bone which has wounded the lateral wall of the pharynx leaves a very distinct impression, and the patient is not able to determine whether it is still there or has passed into the food passage—fish-bones, meat-bones, the bristles of tooth-brushes, pins, buttons, coins, and the different things found in the lower pharynx or larynx. We will save time if we first spray a four-per-cent. solution of cocaine all over the middle pharynx. First use a tongue depressor and examine the pillars of the pharynx and tonsils very carefully, as bones are frequently caught in these. The tongue may be depressed so low that the top of the epiglottis can be seen without a laryngeal mirror. Examine all this surface. Now use a laryngeal mirror and see if possibly a small bone is lodged between the base of the tongue and the sides of the pharynx. We will have to look very carefully to discover the bristle of a tooth-brush, or a very fine fish-bone; they appear no more prominently than a white line, in the laryngeal mirror.

If the foreign body cannot be seen in the middle pharynx, examine the larynx very carefully. If it is in the larynx we shall have such laryngeal symptoms as coughing, huskiness of voice, and possibly difficult respiration. Another location should not be neglected, and that is the pyriform sinuses. The author removed a large wooden tooth-

pick from the right pyriform sinus a short while ago. The patient had been whittling this piece of wood, and putting it in his mouth, inadvertently drew it into his throat. This could not be seen with the mirror during ordinary respiration, but only when the patient made extraordinary inspiratory efforts.

Once the foreign body is located, we should be able to remove it without much difficulty. Laryngeal forceps with a short bite are more easily applied than those with long opening blades. Every man who does throat work should have at least two pairs of these narrow opening forceps, one opening antero-posteriorly and the other laterally. The difficulty with most all these forceps is that the length, which is bent downwards, is too short, and the curve is not apt to be exactly right.

In speaking of laryngeal applications, the author said that the applicator to reach the vocal cords should certainly be bent down three and one-half inches, and oftentimes four inches. This is also true of the proper length of laryngeal forceps. If a foreign body has entered the food passage it will, as a rule, pass safely into the stomach. We may endeavor to locate it by introducing the finger and then later carefully using some variety of probang, such as the umbrella probang or the ingenious coin-catcher. Foreign bodies, if left to the judicious management of Nature, will often do less harm than if they are handled by the too enthusiastic practitioner.

#### THE USE AND ABUSE OF HYPNOTICS IN INSOMNIA.

The use of hypnotics in insomnia is simply the use of symptom remedies; insomnia is a symptom, not a cause of disease nor a disease. Sleep is essential to the welfare of the organism in the same sense that food is. Deprivation of one or the other causes death in about the same period of time.

The use of hypnotics, therefore, should be temporary while the underlying cause of the insomnia is being removed or palliated. Nor, indeed, is it well at the outset to employ hypnotics without trial of other measures. Aside from the removal of somatic causes for sleeplessness, various general methods may be employed. One of the best is a bath at 104° F. for five minutes. The general cutaneous vascular dilatation, increased by rubbing with a coarse towel, is frequently followed by a good night's rest. Warm liquid food, as a glass of hot milk, or a bowl

of soup, will often give satisfactory results. In fact, some of the hypnotics which, on account of their insolubility, must be given in considerable quantities of hot liquids, owe not a little of their reputation to the vehicle in which they are administered. In debilitated individuals, a glass of stout or whiskey in hot water (hot Scotch) may work wonders. In tired subjects, strychnine sulphate in moderate doses acts as a hypnotic, not because it makes a too tired individual just tired enough to sleep, as a distinguished professor of medicine would have it, but because strychnine dilates arterioles. Sometimes stimulation of the emunctories, as by sodium sulphate, again in hot water, taken at night, will be followed by sleep, particularly in gouty subjects, not because it is hypnotic, but on account of its action on liver, intestines, and kidneys. Methods which relieve pain—position, topical applications—are hypnotic.

Sleep is accompanied by cerebral auemia and systematic cutaneous vascular dilatation. Any method which produces these effects will tend to the production of sleep. When these all fail, and often they do, hypnotics must be resorted to. The safest only should be chosen; they are chloralamide, pellotine, paraldehyde, and trional.

The abuse of hypnotics comes from two sources: (1) careless and ignorant physicians, and (2) conscienceless prescribing druggists. The careless physician prescribes for the symptom insomnia, little caring whether it be due to cerebral degeneration, organic cardiac disease, obstructive pulmonary disease, latent gout, or functional intestinal derangements of hysteria. The ignorant physician uses opium or its alkaloids, not knowing that these are narcotics, clubs a patient into insensibility, and calls it sleep. Here commences the opium habit, or, not believing in "new-fangled" remedies, he keeps closely to chloral, and either adds to the list of chloral fiends or terminates the life of one who is suffering from an unrecognized heart lesion, the cause of the insomnia. Or, again, he may be a therapeutic nihilist—a polite name for the therapeutic ignoramus—and finding that drugs when administered by him have but slight beneficial effect, concludes that they have none at all, launches out with a combination of drugs, and succeeds in making his patient sleep because, with all functions overwhelmed, he can do nothing else.

The dangers of hypnotics are immediate (death) or remote (interference with nutri-

tion). The possibility of habit is always to be borne in mind. Druggists are responsible for a large share of the abuse of hypnotics. They openly prescribe hypnotics in doses far exceeding those considered safe, and further, repeat prescriptions containing hypnotic drugs even when the prescription distinctly forbids it. In England sulphonal is sold as openly and carelessly as are the ordinary necessities of life. With equal ease coffee can be purchased for breakfast and sulphonal for bedtime. The same is true in this country.

The only remedy lies with the physician. Let him study his materia medica, learn his therapeutics, and apply intelligently what he has learned. Then, and then only, may we get the best results with the fewest disadvantageous symptoms, do the most for our patients, and, after all, rest with a consciousness of duty well performed.—*Post-Graduate*, May, 1898.

#### PREScriptions FOR ACNE.

The following prescriptions are given in the *Klinische Therapeutische Wochenschrift* of June 15, 1898:

- ℞ Pure resorcin,  $\frac{1}{4}$  drachm;  
Zinc oxide, 40 grains;  
Terra silica, 7 grains;  
Benzoated lard, 2 drachms.

Apply to the part twice a day.

Or,

- ℞ Beta-naphthol,  $2\frac{1}{2}$  drachms;  
Precipitated sulphur, 2 ounces;  
Vaselin and soft soap, of each 1 ounce.

This is to be rubbed on the face for fifteen or twenty minutes daily and afterwards to be removed and the part dusted with talcum powder; or we may use:

- ℞ Precipitate ointment, 1 drachm;  
Subnitrate of bismuth,  $\frac{1}{2}$  drachm;  
Ichthyol, 30 grains;  
Vaselin, 6 drachms.

Apply at night.

#### THE AFTER-TREATMENT OF NASAL OPERATIVE WOUNDS.

The *Post-Graduate* in a recent issue has an article by Dr. RICE upon this topic. He speaks of the importance of this subject, but covers the ground quickly. It is important that the nasal chambers should be as clean as possible before the operation. We have in mind, in this connection, principally wounds of the nasal septum made by cutting. A simple method of cleansing the

nose before making an incision is to spray with one- or two-per-cent. solution of cocaine, which reduces all swelling, and then the nostrils can be washed with the nasal douche cup and Seiler's antiseptic tablets, or Dobell's solution, or the nostrils sprayed with weak solutions—1 to 10,000 of mercuric bichloride, or of peroxide of hydrogen twenty-five per cent. Washing the nose before operation is reasonable, rather than absolutely necessary, because it is not possible to get the nasal chambers in an antiseptic condition.

The second important rule to be followed is never to leave a nasal operation uncompleted. Any piece of cartilage or bone, half detached, which is allowed to remain, furnishes a pocket, prevents proper drainage, and uncomfortable septic symptoms will surely follow. There are a good many difficult cases where we are required to remove cartilage and bone, but we must take the time necessary to leave a smooth surface, even though we have to apply cocaine, and work at the removal of the tissue several times during the one visit of the patient. If the tissue is removed in a cleanly, thorough manner, there will be no further trouble. In nineteen cases out of twenty, even if a small artery be cut into, bleeding ceases spontaneously after a few minutes. Keep the patient at your office until the bleeding has subsided. The patient is then instructed to blow the nose thoroughly to remove any pieces of cartilage or bone and the blood-clot which has formed. Then the nostril, and, in fact, both nostrils, may be filled with the compound stearate of zinc and boric acid powder. This is the protective covering which the author has found most useful in preventing septic absorption through the wound, and it should be insufflated into the nostrils twice a day, or three or four times after the cutting. He does not approve at all of washing the nasal chambers after operating, as it prevents healing and keeps the surface exposed to septic influences. The majority of cases of operation will do best by using the zinc and boric acid powder for a week or ten days after the cutting.

If the patient is kept at the office for half an hour after the operation we shall not be surprised by any secondary hemorrhages on the street. There are a few cases where the bleeding is so persistent as to require a tampon of some sort, but these are very few, and the case is always complicated by the use of any plug, because of the much greater

probability of septic manifestation. But if an artery continues to bleed, we must either insert cotton or gauze wet with some styptic solution, or apply the galvano-cautery point. It is difficult to apply the cautery where there is a great deal of blood, and we do not like the wound made by the cautery where the saw has been previously used. We should say the best method is to insert sterilized gauze moistened with a styptic solution.

There is not much use of removing the tampon before forty-eight hours have elapsed. When it is removed, the nasal chambers should be washed with an antiseptic solution and the wound covered with the boric acid powder. Leave a nasal wound alone as much as possible. The results of the procedure just described are, in the author's experience, very satisfactory.

#### APPENDICITIS.

The editor of the *Louisville Journal of Surgery and Medicine* for July, 1898, says that in the previous issue, in a few words, notice was made of the fertile subject of appendicitis. The discussion of the papers on this subject in the Surgical Section of the American Medical Association, at Denver, was telling emphasis to the criticism made. Careful, clear-thinking, experienced heads insistently declared for opposing views, while there was the usual corroboration of both sides by the less weighty and less informed. Not a little of the spirit shown was sharp, probably bitter, and possibly at times even personal. We are all somewhat prone to defend our own views, and seek the bubble, reputation, with our own mouths. It was a question if the discussion did any good; it is almost a certainty that it did harm. Radicalism fails to convince the courageous conservative; it leads to danger the incompetent and vacillating; it discourages and routs the expectant and hopeful. In questions which involve not only life and death, but as well the reputation of the surgeon, the consent of the patient, facilities for success, etc., the theoretical must yield to the practical. Even if we accepted the dictum that a tender appendix should always be excised—though a congested liver, a painful kidney, a swollen spleen, an inflamed intestine may be allowed to declare its course—there must arise the reflection that practically such radicalism can never become popularly accepted, hence to urge it is to discourage rather than promote concert of action. In principle it is true that an

offending appendix is better out, not because it is always a source of danger, but because no judgment can declare when it is not; but in practise it is equally true that the best interest of the patient cannot always be served by radical adhesion to fixed laws.

Here, as elsewhere, the survival of the patient is through the fittest of conditions. These conditions must be controlled by the judgment of the surgeon. To obtain definite data, a point of departure must be agreed upon. It is clear not ten surgeons in this country operate on all cases of appendicitis as soon as the diagnosis is made, however much they may desire to do so. Many of the remainder who follow these ten in theory are far behind in practise. The immense majority are conservative in practise, whatever may be their theory. The general practitioner is utterly unconvinced. Between these two extremes is fixed the great gulf of death from indecision and neglect.

An eminent operator said in this discussion: "There can be no compromise!" But is it true? Do not arbitration, concession, daily and hourly in our lives protect and strengthen both our dignity and our security?

Not only is a compromise advisable, but at present it is unavoidable, and is entered into every day by the very radicals who oppose it.

The general practitioner having arrived at a diagnosis will rarely willingly call into consultation the surgeon who he knows has already made up his mind; who he knows will not *consult* with him, but will dictate an operation in a lesion he himself admits will recover without it three times out of four. Such uncompromising absolutism not only humiliates the physician, but scares both him and his patient away till the time of safety is past.

Though it is true in skilled hands, under favorable conditions, an operation in all cases at the time of diagnosis will probably secure the highest rate of recovery, yet it is true this course is so impracticable we must seek the most acceptable compromise upon which common ground the best results can be secured. This ground we believe to be about the following, as laid down by the writer in a discussion of this subject before the Tri-State Society at the Nashville meeting in November, 1897:

1. All cases which are of the so-called fulminating form demand immediate operation.
2. Primary cases with moderate pain, temperature and circulation may (not always with safety) be watched for twenty-four to

thirty-six hours. If not improved or stationary after this time, operation should be insisted upon.

3. In recurrent cases more circumspection is demanded and little delay permissible.

4. Trial of operation should not be refused even in general septic peritonitis from appendicitis.

The editor is constrained to say again, as he said in the last issue, that the achievement of better results in appendicitis lies less in the line of improved surgery than in the education of those having the case first in hand. When the family physician, anxious for the welfare of his friend, the patient, and uninfluenced in nine cases out of ten by either prejudice or jealousy, clearly understands the essentials of pathology and is assured that certain easily ascertained symptoms and conditions demand a defined step which the best hope and prospect attend, then and then only will imperfect cures and the unnecessary mortality of this frequent and terrifying lesion be reduced to the minimum.

#### *THE TREATMENT OF INCONTINENCE OF URINE IN CHILDREN WITH THE LIQUID EXTRACT OF RHUS AROMATICA.*

In a recent issue of *Treatment* we find that FREYBERGER has used this drug with great success. He gives us a brief summary of the thirty cases of enuresis which he has treated with rhus aromatica.

In all cases spoken of as "cured" at least nine months have elapsed since enuresis had occurred for the last time.

Of the thirty patients treated with rhus aromatica, twelve are boys and eighteen girls; their ages vary from three to eleven and a half years.

At the time when treatment was begun one child suffered from anemia, two from rickets, one from rheumatism, two from chorea, five from morbus cordis, five from large tonsils and adenoids, one from somnambulism, one from pulmonary tuberculosis, and one was microcephalic; while in eleven children no concomitant affection could be found.

One boy suffered from diurnal enuresis; five boys and fifteen girls presented the combined (or continuous) form of enuresis.

The average duration of the treatment was forty days—thirty-five days in boys and forty-five in girls.

The first signs of improvement occurred

on an average on or about the seventh day of treatment; the earliest on the third, the latest on the twenty-third day.

Thirty-three days on an average were sufficient to produce a permanent cure, fifty-three days to effect a permanent improvement.

Eleven boys and seven girls were permanently cured; one boy and nine girls were permanently relieved; in two girls no improvement could be achieved. A relapse occurred in three girls after an interval of some months.

A temporary exacerbation of the enuresis was noted in eight cases, three boys and five girls; it occurred during or towards the end of the first week in five cases, and during the second week in three cases. While this exacerbation lasted the patients not only wetted their beds two or three times every night, but the quantity of urine passed into the bed each time was considerably increased. This interesting, though somewhat unpleasant, phenomenon lasted from four to six days, and in all cases terminated rather abruptly. During this period of flooding the urine was always very pale; its specific gravity varied between 1002 and 1007. Considering the great disappointment which parents must necessarily feel at this apparent change for the worse, the author made it a rule to tell the parents beforehand that such a recrudescence might possibly occur, but that it would not last long, and in all probability would soon be followed by a decided improvement.

It would be rash to claim for *rhus aromatica* the qualities of a specific in the treatment of enuresis in children as long as our knowledge of this drug and its action is based upon the results observed in barely one hundred cases on which reports have been published; but so much may be said in its favor that it appears to be as efficacious as belladonna, that it may be given for however so long without the slightest ill effect, and that good results may be obtained with it where belladonna proves ineffective.

The astringent taste and disagreeable odor of the liquid extract of *rhus aromatica* are sufficiently disguised by *syrupus aromaticus*.

The dose employed was: Five to ten minims for children two to five years old; fifteen to twenty minims for older children.

A very convenient formula is the following:

℞ Ext. *rhus aromaticæ* fl., 10 minims;  
Syrup. *aromatici*, 20 minims;  
Aq. *distillatæ*, ad 1 drachm.

S.: This amount to be given three times a day.

#### THE SALICYLATE OF METHYL IN THE TREATMENT OF RHEUMATISM.

CATRIN in the *Journal de Médecine de Paris* of June 11, 1898, thinks that the usefulness of salicylate of methyl in relieving the pain of acute articular rheumatism is incontestable. It relieves the pain in his opinion more rapidly than does the salicylate of sodium, although it does not reduce the fever as does the latter drug. In his experience it has been an infrequent occurrence to find that the drug materially disordered the stomach. The doses which he commonly employs are stated to be as much as one ounce a day, but we doubt very much whether the ordinary case could possibly ingest this quantity.

In regard to the use of the salicylate of methyl locally, the author thinks that bands of tarlatan soaked in salicylate of methyl may be wrapped around the joint and covered by an impermeable dressing, with great advantage to the patient.

#### STRYCHNINE IN ALCOHOLISM.

FEDEROFF (*Revue de Thérapeutique Médico-Chirurgicale*, June 1, 1898) has used strychnine in twelve cases of alcoholism with the following results: He believes that the catarrhal processes associated with this condition are rapidly ameliorated and that neurasthenic tendencies are favorably influenced. Thus insomnia and other grave nervous troubles rapidly disappear, the strychnine seeming to produce sleep, so that the patient rested an ordinary length of time for five or six days. The strychnine also seemed to dissipate the nervous unrest of the patients, relieve the pains of which they complained, and in this way aided in producing a cure. To this extent he believes that strychnine is a cure for the alcohol habit, but he does not think that it has any definite specific influence. [This conclusion we think to be correct.—ED.]

#### EXTRAORDINARY CASE OF HORSE-BITE; THE EXTERNAL EAR COMPLETELY BITTEN OFF AND SUCCESSFULLY REPLACED.

The following interesting case is reported by Dr. BROWN in a recent issue of *The Lancet*:

On March 2, 1898, at about 4.30 P.M., when present at an auction, he was asked to attend to a boy, aged fourteen years, whose ear had been bitten off by a vicious horse. He presented a hideous appearance, the greater

portion of the pinna, together with a semi-circular flap of an inch radius from behind the ear, having been bitten off, leaving only the tragus with a quarter of an inch each of the helix and lobule. Although the case looked so hopeless (as regards disfigurement) he determined to make an attempt to save the ear, as the patient could be no worse off if the attempt failed. He asked for the ear, and after about ten minutes' search it was brought to him, having been found near the horse in the stable yard. It was of a dirty drab color and the posterior flap was curled up in a roll. He had no instruments or dressings with him, and it would have taken half an hour or more to procure them, which delay would have rendered the attempt to preserve the ear useless. He therefore procured some common needles and thread, and after washing the ear in warm water he proceeded to sew it on by inserting a suture above and another below, followed by three behind and three before. The posterior flap had to be unrolled before he could stitch it, and owing to the needles being straight there was great difficulty in placing the sutures in the concha and the fossa of the antihelix. He then placed a roll of cotton-wool behind the ear to support it, and having wrapped it in cotton-wool and covered it with a silk handkerchief sent the boy home. As soon after as possible he removed as much of the wool as he could without disturbing the wound, and after dusting the surface with iodoform, wrapped the ear in cotton-wool and Gamgee tissue.

On March 7 he removed the dressings, washed the ear with a warm solution of bichloride of mercury (1 in 1000), dusted the surface with iodoform, wrapped the ear in iodoform gauze, and packed it round and covered it with cotton-wool. On the 10th he renewed the dressings and removed the sutures. On the 14th a small portion of the lobe sloughed away. On the 16th the patient looked rather anemic and felt weak, so he was given a mixture containing sulphate of quinine and tincture of perchloride of iron. The same treatment was adopted throughout, the dressings being renewed every second or third day until April 7, when they were allowed to remain on until the 12th, when the ear was completely healed. The patient's diet consisted of plain food, together with beef tea, eggs, etc. He is a healthy, intelligent lad, who has survived several accidents, his body being covered with scars from burns. On one occasion it

was necessary to transplant six skin-grafts from the calf of his leg to his thigh to replace skin which had been destroyed by burns.

This case, the author considers, shows what valuable results may be brought about by antiseptic treatment and making prompt use of whatever comes handy when the proper instruments, etc., are not available.

---

*THE INFLUENCE ON THE BLOOD OF  
SYPHILITICS PRODUCED BY INTRA-  
VENOUS INJECTIONS OF  
MERCURY.*

In *La Presse Médicale* of May 18, 1898, LINDSTROEM contributes an article upon this subject. He believes that intravenous injections of mercury are of very great value when it is necessary to put a patient under anti-syphilitic treatment of a heroic character. After quoting a good deal of the literature on this subject he proceeds to give us the results of his treatment. Thus in one case, a soldier twenty-five years of age suffered from a chancre, followed by a discrete roseola. Thirteen intravenous injections were practised. Seven of these consisted in the use of one-sixtieth of a grain of corrosive sublimate. In six others one-thirtieth of a grain was used at an interval of six days. Under this treatment the quantity of the red cells increased 500,000 after the early injections, and this augmentation increased as the injections were continued. After as much as one-twentieth of a grain was injected the corpuscles rose to 6,620,000, but after the injections were stopped the quantity of the red cells diminished considerably. Along with the augmentation in the quantity of the red cells there was a coincident diminution in the intensity of the syphilitic eruption. When subcutaneous injections of benzoate of mercury were used the number of red cells did not increase as they did after intravenous injection. The quantity of hemoglobin was increased and continued to increase under the intravenous treatment. The white cells were decreased in number by this treatment. The ordinary flow was increased by intravenous injections and the quantity of urea equaled one and a half ounces a day, but after the seventh injection diminished in quantity.

In regard to the elimination of mercury the author found that it commenced in two hours after the intravenous injection, the maximum occurring after eight hours. An analysis of urine after twenty-four hours showed the

presence of mercury. He therefore concludes that minute doses of mercury introduced directly into the blood increase the quantity of hemoglobin in the red cells, diminish the white cells, but do not very materially influence the syphilides. In still another case a patient of twenty-two years, with an intense roseola and polyadenitis, received subcutaneous injections of corrosive sublimate, thirty-one being given during the space of forty-five days. Under the use of these subcutaneous injections the red cells markedly increased, but equally good results with intravenous injections did not seem to be obtained.

After quoting other cases this author concludes that the direct introduction of mercury into the blood exercises a most useful influence and that improvement takes place almost at once. Small doses should be given at first and gradually increased. If, however, too large doses are used, or it is continued too long a time, mercurial anemia may develop. In severe cases, therefore, it would seem that this method of treatment is advisable. It is hardly necessary to add that careful antiseptic precautions should be maintained.

#### THE THYROID THERAPY.

The *Northwestern Lancet* of June 15, 1898, has in it an article on Thyroid Therapy by HALDOR SNEVE. The conclusions which he reaches are as follows:

1. The thyroid gland produces a secretion of the greatest importance to the metabolism of the body. Absence of function produces cretinism if congenital, myxedema if acquired.

2. Simple hyperplasia (simple goitre) does not produce marked pathological disturbances, but the writer believes it to be a larvated form of exophthalmic goitre, and that so-called "nervousness" can be found in the vast majority of cases.

3. Hyperplasia associated with disturbance of the cervical sympathetic is the disease known as exophthalmic goitre.

4. Surgical interference in diseases of the thyroid gland should be limited to the removal of neoplasms; thyroidectomy in exophthalmic goitre is unphysiological, irrational, and dangerous.

5. In the majority of cases of exophthalmic goitre, medicinal hygienic treatment, rest, galvanism through the neck (two to five milliamperes), tonics, sodium phosphate and thymus gland will effect amelioration.

In cases refractory to medical treatment where life is threatened, section of the cervical sympathetic should be practised.

6. Many cases of neurasthenia are cases of masked exophthalmic goitre and should be treated accordingly.

7. Thyroid therapy is specific in sporadic cretinism, myxedema, and simple goitre, and removes obesity.

8. Thyroid extract increases the unpleasant symptoms in exophthalmic goitre, and is a reliable test also in the masked form of this disease.

#### THE TREATMENT OF HEMORRHAGIC NEPHRITIS.

The *St. Petersburg Medicinische Wochenschrift* of May 16, 1898, contains an article by KRAMER, of Dorpat, in which he mentions the dietetic and hygienic treatment of chronic hemorrhagic nephritis and the use of ergot, tannin and citric acid for excessive hematuria. He then goes on to describe how he has used methylene blue with advantage in such cases, and cites a case of a man of sixty-four who came to him suffering with swelling of the lower extremities, loss of appetite, feeble heart, and the dark red colored urine due to the presence in it of blood coloring matter. Tannin, calomel, acetate of lead and salol did not exercise any favorable influence. Kramer then decided to give the patient methylene blue, using two to three grains once, twice or thrice a day. As a result of this there was a decrease in the hemorrhagic evacuation and in the quantity of albumen which the urine contained. He detailed three other cases in which a similar method of treatment was resorted to with advantage and believes that methylene blue is our most efficient agent in controlling rapidly and absolutely the blood in the urine.

#### THE GOOD EFFECTS OF IODIDE OF ARSENIC IN INFANTS SUFFERING FROM SCROFULOSIS.

The *Journal de Médecine de Bordeaux* of June 19, 1898, contains an article by SAINT-PHILIPPE upon this subject, a subject which is well known to medical men in general. He points out that under the use of the iodide of arsenic improvement takes place in the condition of the skin, the mucous membranes, the various viscera, and finally that the glandular condition is ameliorated. Even in those forms of skin disease which are infectious, as for example impetigo, he finds that the use

of iodide of arsenic is of great value. He prescribes it in the following form:

- ℞ Iodide of arsenic, 7 grains;  
Distilled water, 1½ ounces.

Dissolve and give 5, 10, 20 or 30 drops of this solution a day, according to the age of the child.

As the remedy is an active one it is wise, in his opinion, to commence with a small dose—for example, only a drop may be given morning and night, and this dose gradually increased. In very susceptible individuals dyspeptic symptoms may arise and slight nausea may develop; diarrhea may also come on, and in this case the dose must be cut down.

#### THE TREATMENT FOR INTESTINAL WORMS.

In the *Revue de Thérapeutique Médico-Chirurgicale* of June 1, 1898, LYON tells us that the patient should have nothing for his dinner or supper save a bowl of milk or soup. The bowels should also be carefully washed out in the evening by an injection and the vermifuge taken, a purgative and rectal injection being used the next morning. He believes that the sulphate of pelletierine in the dose of two to four grains is best given in a mixture containing tannin; thus he prescribes:

- ℞ Sulphate of pelletierine, 3 grains;  
Tannin, 15 grains;  
Distilled water and simple syrup, 2 ounces;  
Essence of orange, 10 drops.

This is to be taken in two doses at half-hour intervals. Ten minutes after the ingestion of the second dose a large draught of Hunyadi water should be taken. Such a prescription should not be given to a pregnant female, nor to very old persons. In other instances the following prescription may be used:

- ℞ Oleoresin of male-fern, 1 to 2 drachms;  
Syrup of ether, 1 ounce;  
Mint water, 1 ounce;  
Syrup of acacia, 3 ounces.

To be taken in two doses two hours apart. Or the oleoresin of male-fern may be given in capsule with calomel, seven grains of the oleoresin and one grain of calomel to be put in one capsule; twelve to sixteen of these capsules are to be prepared, and two should be taken every ten minutes. One hour after the last capsule is administered a purgative may be given.

Lyon points out the fact, which is well known to therapists, that castor oil should not be given after male-fern as it favors the intoxication with filicic acid. For the re-

moval of round worms Lyon advises the use of santonin combined with calomel; two to five grains of santonin may be given with a grain or two of calomel, divided into three cachets. For the removal of seat-worms Lyon suggests injections with salt water, the use of castor oil or of thymol (three grains in two ounces of olive oil). In other instances glycerin suppositories may be used with advantage, or, again, a solution of boric acid may be employed.

#### THE INFLUENCE OF FORMALDEHYDE UPON DIGESTION.

The remarkable properties of formaldehyde as an antiseptic have caused FINOISSIER to study its value as an intestinal antiseptic and also to determine its influence upon the digestive ferments. In regard to the digestion of starches he took a series of flasks and placed in them ten cubic centimeters of starch-water, to which he added two cubic centimeters of saliva and ten cubic centimeters of a dilute solution of formol. These flasks were then exposed to the temperature of the body. Three hours afterwards it was found that the formol exercised a feeble retarding influence upon the conversion of starch into sugar. In regard to the amylolytic power of pancreatic juice he found that there also occurred a slight retardation. Upon the action of pepsin in converting into peptones considerable delay took place, and concerning a similar action of trypsin the same results were obtained. Upon the coagulation of casein formol exercised a distinct inhibitive influence: thus in the proportion of 1.5 in the 1000 the time necessary for coagulation of caseation was twenty-five minutes, whereas when no formol was used it was but two minutes. It would seem, therefore, in general terms that formol exercises an inhibitive influence upon digestive processes, but that this is not sufficiently marked to prohibit its use in those cases in which it seems advisable to administer it as an intestinal antiseptic.—*Revue de Thérapeutique Médico-Chirurgicale*, June 1, 1898.

#### THE INTRANASAL USE OF MEDICATED OILS OR OILY FLUIDS.

A recent issue of the *British Medical Journal* has in it an article by Dr. EWART on this interesting subject. He says that in diphtheria the occasional occurrence of a long period of infectiveness after apparent recov-

ery has suggested an important precaution, that of keeping, throughout the attack and for some time after recovery, the nares protected by some antiseptic and healing application. For some years the writer has made this a rule of nursing in his cases, and carbolized oil (1 in 60) has been systematically introduced either by the swab or by the dropping method. A very small quantity of oil repeated twice a day will suffice. It is not improbable that after the pharynx has cleared itself of membrane some of the infection may linger in the large mucous tract above, especially in the absence of any cleansing treatment, and that in reported instances of late infectiveness the mischief may have really resided in the nasal fossæ. At any rate, it is believed that this precaution, if carried out methodically, might materially diminish the risk of a late transmission of diphtheria during convalescence.

In affections of the nostrils, nasopharynx, and sinuses, the local application of oil does not appear to have occupied the therapeutic position which some of its advantages seem to deserve. It is not referred to in current literature, and does not seem to have been practised with frequency, if at all. This circumstance may have been the result of the only drawback which the method presents, namely, that it is somewhat unpleasant to sensitive persons, and unless used with discretion, apt to nauseate. On the other hand, its simplicity and its efficacy in fulfilling the objects for which it is prescribed are recommendations. Its good results are manifest chiefly where it is locally applied to the mucous membrane affected; but it is also beneficial in those respiratory affections in which the trachea and the larger bronchial tubes suffer jointly with the nose and nasopharynx, and also in some cases of neurotic dyspnea or asthma in which the nose is the seat of irritation. Its action in these cases would be one partly reflex, and therefore distinct from the results obtained by the strictly local method of intralaryngeal injections continued for long periods; moreover, it does not claim to cure the affections in question, but merely to alleviate their symptoms and to obviate the recurrence of attacks.

The same mode of application is suitable to all cases. A small quantity of carbolized oil (1 in 60), flavored with some essential oil such as that of almond or bergamot, is introduced into the nostrils whilst the patient is lying down with the head thrown back. A

small glass syringe fitted with a spray nozzle is best, but failing this a common nozzle will answer; or the oil may be simply dropped into one or both nostrils. The patient should be directed to turn the head from side to side to facilitate the spreading of the oil. Where the object is local treatment of the frontal sinuses, it will be necessary to throw the head still further back and to keep it in that position for a minute or two. If the quantity of oil should have been excessive, or if it should have been dropped instead of sprayed, it will trickle down the back of the throat, and this often excites some nausea. The quantity which has generally been used is about a saltspoonful, or fifteen drops, but even a less quantity may be found useful, and the objection stated may then not arise. The oil may be made the vehicle for various remedies. Recently, for instance, in a case of recurring epistaxis, in which the source of hemorrhage was thought by the patient to be in the left frontal sinus, tannin was added to the oil, and the latter was felt by the patient to reach the spot in question. In many cases stimulation is wanted quite as much as, or even more than, mere protection. The author has therefore availed himself of a well known formula:

Menthol,  
Thymol, 22 gr. j;  
Ol. olivæ, q. s. ad 3 jss.

This has been preferred by some patients to the oil, and in others has been found efficacious where the latter did not relieve the symptoms. The stimulating solution is especially useful in neurotic cases.

The conditions in which the local use of medicated oil may be found of value are the following:

In continued pyrexia the drying and caking of secretion in the nasal cavities are a source of much discomfort; the mouth often has to be kept open in consequence, and the dry tongue of fever is the result. In these cases, as in the following, the quantity of oil required is very small provided it be thoroughly applied, and this can be done by introducing a thin swab of twisted cotton-wool or of lint charged with the oil.

Nasal dryness and fetor are also apt to occur in all varieties of continued hurry of breath, but particularly in that which belongs to heart disease with broken compensation. Among valvular diseases, advanced mitral stenosis, with or without associated regurgitation, in which there is considerable venous congestion, is that most often accompanied

by these symptoms. The ozena-like odor was formerly supposed by the writer to be dependent upon some local lesion special to this disease; but it is probably explained simply as a result of permanent congestion and of the drying of a mucous membrane lined with secretion. The comfort to the patient and to the physician arising from this treatment is well worth the small trouble which it gives.

Among the obstructive and nasopharyngeal troubles permanent or progressive structural defects, such as narrowing of the passages, polypi, adenoid growths, etc., are curable only by surgical means. But striking alleviation, of any superadded congestion or catarrh may be brought about by the use of oil, which is particularly indicated for impacted foreign bodies. Much benefit may accrue in children suffering from large tonsils or adenoid growths, and from nocturnal restlessness and cough, if the mucous membrane can in this way be kept free from irritative congestion, swelling and dryness, by protecting from the results of open-mouth breathing. The same applies in the adult, where the nostrils are blocked by a polypus or by secretion and swelling.

Dry nasopharyngeal catarrh and granular pharyngitis are both susceptible of much relief. The treatment is specially adapted to cases in which dense, adhesive mucus forms scabs on the pharynx, and leads to the well known distressing symptoms; and as a protecting agent it also may be of much service in granular pharyngitis. Acute catarrhal pharyngitis, if submitted to this local treatment sufficiently early, when the sore, raw feeling, or the stiffness and pain limited to one spot, with which the affection often begins, are first perceived, would probably be manifestly relieved, but there are no cases to report. This might be the means of checking the usual extension of the catarrh to the mucous membrane of the trachea and large bronchi.

Bronchial catarrh of the large tubes, or common chest cold, is frequently the sequel or the concomitant of nasopharyngeal catarrh. This conjunction led the writer to try the treatment in his own case, and he was much impressed by the relief afforded, not only to the nasal catarrh, but to the chest symptoms, including retrosternal pain and rawness, painful cough and expectoration. He has since then observed equally satisfactory results in other cases.

It is difficult to explain how a local appli-

cation in the nose can relieve the chest, since it is doubtful whether the oil, although spreading so rapidly, can find its way downwards into the air passages. The influence is probably one brought about by associated nerve agencies. If, therefore, we regard the resulting relief as one merely reflected from the pharynx, we can hardly expect that the nasal method will be of much service in bronchitis of the smaller tubes. On the other hand, the direct application of oil might perhaps be of use, and one at least of the cases narrated is an instance of the success of the treatment in the bronchopneumonia of diphtheria. The results noted from the indirect or intranasal method cause us to inquire again whether the more frequent use of intralaryngeal injections might not be of advantage. Hitherto they have been chiefly employed in chronic pulmonary affections; but if directed to the cure of the more acute catarrhs of the large tubes their efficacy might be more manifest, and probably many a protracted chest affection might be avoided or considerably shortened in duration. It may be thought that this is too powerful an engine to apply to small work; but the intralaryngeal injections are really not troublesome to the patient if successfully performed, and their performance presents no difficulty to any one familiar with the laryngoscope.

On the other hand, it would be premature, without previous trial, to recommend intralaryngeal injections in bronchopneumonia, and their desirability in acute bronchitis must also remain an open question till further experience has been gained.

It is well known that in a proportion of cases of asthma the affection is connected with some nasal trouble, usually a congestive hypertrophy of the mucous membrane; and the opinion has been held that asthma itself is a congestion and swelling of the mucous membrane. The late Sir Andrew Clark took that view. Only a proportion of these cases yield to local treatment by the galvanocautery, or to local medication such as that by perchloride of mercury, carbolic acid, and quinine, formerly recommended by Sir Andrew Clark. Among the local methods which might still be resorted to in the unrelieved cases the present one suggests itself for trial.

#### *ACUTE PNEUMONIA IN CHILDHOOD.*

In the *Edinburgh Medical Journal* for August, 1898, CARMICHAEL tells us that we have, as yet, no special treatment for acute

pneumonia. The antitoxin has not yet been discovered, but this is a line of research well worthy of attention. All we can do is to treat each patient according to the special needs of the case, meeting symptoms as they arise by rational means. In all cases hygienic measures, including diet, are all-important. The patient should be in a well-ventilated room of mean temperature. The author finds a tent-bed invaluable, hung round inside with wet towels sprinkled with eucalyptus or creosote, or other antiseptics. In very severe cases, with much cyanosis, the inhalation of oxygen mixed in the air of the tent often proves of signal benefit. The dieting should be conducted on the general principles applicable to all febrile affections—light, easily digested nutriment, in such quantity as the patient can digest. Overfeeding is harmful, as likely to bring on vomiting and diarrhea, which are complications always to be dreaded. Continuous and routine poulticing is now discarded, poultices being used as other therapeutic means, according to the necessities of the case. A stimulating sinapism occasionally applied all over the chest for half an hour or an hour is often very serviceable, this being replaced by a pneumonia jacket of Gamgee tissue; when the temperature is high and the skin is not acting, a moist continuous poultice of soft flannel and jaconet, moistened with boracic solution, is very grateful to the patient. By keeping up a local as well as general diaphoresis, relief is given to the engorged lung, whose blood-vessels are in a state of hyperemia and permanent dilatation, the cutaneous blood-vessels, which are in the opposite condition of high tension, being thereby relieved.

As no drug yet known has any special influence on the disease, we must treat the patient by endeavoring to assist Nature in her efforts to maintain a compensatory physiological balance in the functional activity of the various organs. In the reference already made, in regard to dieting, the writer has indicated the necessity of due attention to the digestive functions. The respiratory embarrassment can be best relieved by keeping up a continuous local and general diaphoresis, as already indicated. This should be assisted by the exhibition of non-depressing diaphoretics, such as liq. acet. ammoniæ and sp. etheris nitrosi, a combination which has well stood the test of experience. The nitrous ether is most valuable in relieving the general vascular tension apart from that of the lung. Alcoholic stimulants are of

great value, especially in bronchopneumonia. They must be administered in suitable doses, according to the exigencies of the case and the state of the pulse. Next in importance as a stimulant the author regards strychnine. The indications for its use are similar to those of alcohol, and it may be given with advantage at the same time. He regards it as of more value in the acute respiratory affections of children than in adults, on account of its action on the cardiac respiratory centers and cardiac ganglia. In children it is well known that the nerve tone is more rapidly lowered from acute disease than in adults, hence the great importance of anticipating this by the timely use of such a remedy.

The use of belladonna in certain cases of acute respiratory affections of infants is one of the most striking therapeutic facts the writer knows of. The cases in which it is indicated are those, particularly of infants, attacked with acute congestive bronchial catarrh in the early stages. It is well known that in these congestive conditions, which are accompanied by more or less bronchial spasm and collapse of the lung, its action in soothing the afferent and efferent nerves in the bronchial walls, and stimulating the respiratory center, is most marked. It has no beneficial effect in the later stages where the alveoli are involved, but its timely use in earlier stages of the disease is attended with striking results.

The author's remarks on the drug treatment of acute pneumonia would be incomplete, he says, were he not to refer to digitalis, and he only does so to condemn its use as a routine remedy. He does not for a moment undervalue the importance of employing this drug in cases where its use is clearly indicated—feeble pulse with weakness of the left ventricle and diminished arterial tension. Such conditions obtain occasionally, but not frequently, in the pneumonia with large lobar consolidation. On the other hand the condition of the arterial system clearly contraindicates its use. The state of the blood-vessels in the affected part is that of distention and paralysis, the systemic arterial circulation being in a high state of tension, with an enfeebled and distended right heart. In such cases we have no proof that digitalis has any power in restoring the tone of the blood-vessels in the affected part. It cannot act on the right heart without more powerfully (on account of the greater muscular area) stimulating the left ventricle to congest the affected lung by

"diminishing the vascular area" (Loomis). Heart failure in lobar pneumonia would appear to be due to two principal causes—the depressing effect of the toxins on the nervous center, and of a high temperature on the heart muscle. If this be so, there are no indications for digitalis, but rather for such remedies as act directly by stimulating the nerve center on the one hand, relieving the local hyperemia on the other. He believes that local and general diaphoresis, occasional purgation, and remedies which stimulate the cardio-respiratory centers, are the most appropriate means of combating this condition.

The use of large doses of phenacetine or antipyrin is in the author's experience not useful, often harmful, in both forms of pneumonia. In small doses, however, they are often of service in allaying nervous irritability and restlessness. In hyperpyrexia we must trust to the wet pack, or tepid bath, or the application of cold by ice-bags, or otherwise.

The author regrets to find that even yet in these more enlightened days such remedies as ipecacuanha, tartar emetic and squills are prescribed by some physicians. There is no indication that he knows of, but a distinct contraindication, for their use. Children suffering from pneumonia require rather stimulation than the exhibition of depressing remedies such as these.

#### INTRACEREBRAL INJECTIONS OF ANTI-TOXIN IN THE TREATMENT OF TRAUMATIC TETANUS.

Trustworthy as the antitoxin treatment has shown itself to be as a preventive of tetanus, it is comparatively of little avail once the disease has become established. Pondering on this state of things, some months ago E. Roux and A. Borrel came to the conclusion that the frequent failure of the antitoxin in cases of developed tetanus was due to the failure to catch up with the toxin, so to speak. In other words, they said to themselves, while the antitoxin was floundering about in the blood the toxin was doing its deadly work on the nervous centers; the two, although so close, did not come in contact.

To remedy this defect of the treatment, they reasoned it would be necessary to inject the antitoxin into the central nervous system itself. But the soundness of this view had first to be tested experimentally. Accordingly, forty-five tetanized guinea-pigs were treated with intracerebral injections of antitoxin, and thirty-five of them recovered.

Seventeen others were treated with the antitoxin injected simply under the skin, but in far greater amounts, and only two of them survived. Seventeen check guinea-pigs, not treated with the serum, all died. Roux and Borrel reported on this matter at the recent Madrid International Congress of Hygiene. Their theory has now been successfully put into practice on the human subject, a patient of A. Chauffard's, who in conjunction with Quenu reports the case in the *Presse Médicale* of June 18, 1898.

A healthy lad sixteen years old, a gardener, was injured by a greenhouse sash falling on his hand and crushing the tips of the index and ring fingers. This was on the 8th of April. Four days later the lad presented himself at the Cochin Hospital, where he was treated daily as an out-patient until April 22, when he complained of trouble with his jaw and also of a tooth. The dentist found no trouble with the boy's mouth, but suspected tetanus. Nevertheless he prescribed only a carbolized gargle. On the following day the symptoms had become more pronounced, and the patient was advised to enter the hospital. This he did not do at once—in fact, not until the 25th. He then had decided trismus, with the sardonic grin, but the muscles of deglutition and those of respiration were not yet affected; his intelligence was undisturbed, and there were no paroxysms. In the course of the day he received twenty cubic centimeters of antitetanic serum under the skin. On the following day (the 26th) there was well-marked tetanus of the trunk, but the limbs were still free from contracture.

M. Quenu was now called upon to do the operative procedures required for carrying out the Roux-Borrel treatment. The patient's entire head was shaved, aseptized, and protected with a dressing. Anesthesia was induced with chloroform, and M. Quenu made a small curvilinear incision down to the bone on the right side, the middle of the incision falling in a line drawn vertically from the external orbital process and being eight centimeters distant from that process. The concavity of the incision was directed forward and downward. The little flap was dissected up, and a button of eight millimeters diameter was removed. The dura mater was incised, and the hypodermic needle was passed into the brain to the depth of five or six centimeters. M. Roux himself pressed the piston slowly, injecting between one and a half and two cubic centimeters of serum concentrated one-half (ten parts dried and

then redissolved in five parts), which he and M. Borrel had prepared on the spot. The process of injection, drop by drop, occupied about six minutes. No noteworthy phenomenon accompanied it. The cutaneous wound was closed with three sutures, and the same procedure was executed on the left side of the head. Occasion was taken of the anesthesia to treat the injured fingers radically. The entire operation lasted about three-quarters of an hour.

On the lad's emerging from the anesthesia, some improvement was noted at once, but, as is always observed in severe cases of tetanus that end in recovery, whether spontaneously or as the result of treatment, he still had to go through with a long persistence of the manifestations prior to the favorable turn. On the 29th he received twenty cubic centimeters of antitetanic serum, but this time subcutaneously, and the same amount again on the 1st of May; also ten cubic centimeters on May 2, and twenty on the 3d. It was not until the 8th that he showed decided improvement, and he sat up for the first time on the 18th. During all this time the antitoxin treatment was judiciously supplemented with nutrient enemata, injections of artificial serum, and the administration of sedatives.

The authors explain that the operation was practised at the level of the base of the second frontal convolution, in order to avoid injury to the psycho-motor centers, and yet admit of the serum being deposited near enough to them to find its way to the affected parts by diffusion. They do not seek to attach undue weight to this single case, but they properly insist on the severity of the disease and on the positive character of the evidence afforded in this instance. It seems to us that Roux and Borrel have now made a substantial advance in the serum treatment of tetanus.—*New York Medical Journal*, July 9, 1898.

#### THE TREATMENT OF CHRONIC NASOPHARYNGITIS.

The July issue of the *Memphis Lancet* has an article in it by SOMERS, of Philadelphia, on this subject. He believes it best to discuss our local remedies under the divisions of pigments, ointments, powders, sprays, and vapors. The value of pigments depends upon their accurate application to the area hypertrophied or the seat of the ulcer, should such be present. Under the head of pigments, turpentine with oil of anise makes a

valuable application, especially in acute exacerbations of the chronic affection; it may be diluted with lavender, and any of the essential oils may be used to disguise the odor, anise, as mentioned, being very agreeable to the majority of patients. This should be applied to the nasopharynx with the cotton tuft on a curved applicator several times weekly. In many cases it seems almost impossible to apply the drug on account of the irritable condition of the parts, the uvula immediately being drawn upward and backward as soon as the tongue depressor is placed in the mouth. In these cases a one-per-cent. cocaine spray will greatly facilitate the treatment, or in its place good results are obtained with a spray of five grains of menthol to the ounce of liquid cosmoline or any of the bland oils used for this purpose. A palate retractor is frequently of value, and although somewhat unhandy at first, one soon becomes able to manage it without any difficulty. White's self-retaining is the one the author uses, and he has found it very satisfactory, enabling one to apply the pigment to the proper area desired. It seems to be the custom to apply the remedy to the pharyngeal walls and vault without any evidence of the medicament reaching the part diseased; should the condition be due to ulceration of the posterior end of the middle turbinal, it is impossible in the general way of making local applications to reach the affected parts at all, and it is best to use the rhinoscopic mirror in every case where applications are made to the nasopharyngeal region.

As a stimulating absorbent the following has been found useful in many cases:

- R Iodine crystals, 10 grains;  
Potassium iodide, 20 grains;  
Menthol, 50 grains;  
Glycerin, q. s. ad 1 ounce.

M. Sig.: For local application.

Or the muco-purulent secretion may be materially diminished by:

- R Camphor,  
Carbolic acid, of each 30 grains;  
Menthol, 50 grains;  
Turpentine,  $\frac{1}{4}$  ounce;  
Albolene, q. s.

Sig.: The albolene, or any suitable oil, is added a drop at a time until one drop remains free in the bottom of the bottle.

Nitrate of silver in obstinate cases is valuable if applied to limited areas, and it may be used in solutions varying in strength from ten grains to saturation. As is well known, the application of weak solutions of silver to the mucous membranes is somewhat painful,

while strong solutions if carefully used cause no inconvenience; but caution should always be observed to see that there is no excess of fluid on the applicator and that it does not touch any part but that for which it was intended.

Ointments have not been used to any great extent in the nasopharynx, but they are very serviceable, as they remain for a considerable time after being applied and allow the drugs to exert a continuous action. They are applied in the same manner as pigments and various combinations may be used, the following being of service in the affection described:

- ℞ Ichthyol, 1 part;  
Zinc oxide, 10 parts;  
Wheat starch, 10 parts;  
Lanolin, 20 parts.

Many other combinations will readily be suggested by using pigments in this manner, and often better results are obtained with the ointments than with the latter form of medication. Powders are rarely of value, as they are apt to get into the larynx and produce violent attacks of coughing, even if the utmost care be used in their application, and at the same time a great objection is that it is impossible to apply them solely to the parts desired, as they cover the entire region and more or less obstruct the already diminished respiratory area. Of far more value and utility are the sprays, always being used before other local applications to remove mucus, etc., and they are serviceable to the patient as being readily used at home. With a coarse or fine spray we may apply any drug in solution that seems best suited to the individual case; the alkaline antiseptic spray or wash, depending on the method with which it is used, and known as "Seiler's," being representative in its class. Sprays may be used to cleanse the parts, as the one just mentioned, or as antiseptics, astringents, and sedatives, hamamelis representing the last class.

Vapors or nebulæ are generally used as inhalations for the various forms of laryngeal inflammation, but occupy a distinct and valuable place in the therapy of the affection described in this paper. Their value lies in the penetrating power they possess, the medicated vapor penetrating the recesses of the nasopharyngeal region and, when an oily base is used, remaining in contact with the tissues for some time after being inhaled. Nebulæ may be used either with or without the addition of steam, the choice depending upon the

result desired, and when the mucus is tenacious and clings to the vault of the pharynx, especially at the orifice of the Eustachian tube and adjoining fossæ, we find an alkaline steam vapor will readily cause the separation of the adherent secretions from the mucous membranes, and for this purpose the following will be found useful:

- ℞ Sodii bicarb.,  
Sodii baborate, 33 gr. x;  
Potass. bromide, gr. v;  
Aqua mentha pip., 3 ij;  
Aqua dest., q. s. ad 3 j.

Sig.: Use twice daily.

Inhalations may be used at any time during the day, provided steam is not mixed with them; should hot vapors be desired, the patient must not go into the air for at least one hour afterward, as the mucous membrane becomes relaxed and coryza almost invariably results. It is the best plan to use inhalations at the room temperature during the day and then direct the patient to steam the nasopharynx for five minutes just before retiring for the night; in this way all danger of coryza or of acute exacerbation of the catarrh will be avoided, and after this has been repeated a few times there will be no difficulty in removing the tenacious mucus. The following formula may be used at night as a stimulant; it acts by increasing glandular secretion and stimulating the parts to normal activity:

- ℞ Ammon. chlor., gr. xv;  
Tr. benzoin comp., 3 j.

Sig.: One-half teaspoonful in four ounces of boiling water.

There are a number of satisfactory devices to use vapors that are very useful in office work, while the patient may obtain a vaporizer especially made for this purpose, or the solution desired may be placed in a cup filled with boiling water; over this an ordinary funnel is inverted, and the medicated steam may readily be inhaled. It is essential to see that the patient allows the vapor to pass through the nasopharynx and out through the nose. Although this is usually more difficult to learn than the usual forms of laryngeal inhalations, still no trouble should be experienced on this point.

#### THE PECULIAR SUSCEPTIBILITY OF WOMEN TO THE TOXIC AC- TION OF SULPHONAL.

POLLITZ (*Vierteljahrsschrift für Gerichtliche Medicin*, xv, 2; *Wiener Klinische Wochenschrift*, June 9, 1898) relates the case of a

woman who was treated very successfully for a puerperal mental affection with sulphonal, given to the amount of twenty-two and afterward fifteen grains daily for more than a year, with frequent interruptions of the treatment for weeks at a time. Finally symptoms of sulphonal poisoning appeared—deep-red coloration of the urine and diminution in the amount of that secretion, obstinate constipation, and loss of appetite. The case ended fatally, but it is remarkable that periods of notable improvement in the woman's condition preceded her death. At the post-mortem examination there was found extensive disease of the secernent epithelia of the urinary tubules.

Pollitz calls attention to the fact that the recorded cases of sulphonal poisoning have been in women for the most part. Among twenty-one cases, Schulz found that twenty were in women, and all observers have found that the victims of sulphonal poisoning were anemic to a certain degree. The inference seems reasonable, Pollitz thinks, that certain conditions of the blood, such as chlorosis, have a direct connection with the supervention of toxic phenomena under the use of sulphonal.—*New York Medical Journal*, July 9, 1898.

*CORNEAL ULCERS, VARIETIES AND  
TREATMENT, WITH SPECIAL  
REFERENCE TO SUBCON-  
JUNCTIVAL INJECTIONS.*

WILLETTTS, writing upon this subject, says that in the treatment of corneal ulcers atropine is looked upon as almost a specific, when in reality it is only a preliminary step. It has no germicidal action, and has no bearing on the cure of the disease, excepting that of preparing the parts for reparative action. It paralyzes the accommodation, doing for the eye what a splint does for a fracture—puts the part in absolute rest, which is a recognized factor in the successful treatment of all disease. It relieves the local congestion, which, however, is a symptom only, and seems to have a special action on some varieties that is not applied to others. In phlyctenular keratitis, which is not dependent on micro-organisms, while atropine is not contraindicated it certainly is not indicated, and the patient may be spared the annoyance dependent on its use. This disease, principally one of childhood, is characterized by elevations of the corneal epithelium at the limbus, dependent on the congregation of

leucocytes at the peripheral nerve endings. It is readily cured by the yellow oxide of mercury of suitable strength, together with supportive treatment, in those cases of scrofulous diathesis, or cachexia, from unhygienic surroundings. Analogous to this form is keratitis fascicularis, which, like the former, commences at the margin of the cornea; but this, unlike the former, invades the cornea, generally in a parallel line, dragging after it a leash of blood-vessels, the arrangement of which is pathognomonic of this affection. It yields readily to the same treatment.

The serpiginous ulcers with hypopyon and other forms of corneal infection, such as onyx, require a more radical and prolonged treatment, the benefits of the actual cautery in these infections being infinitely superior to any other method. The author has never seen a single bad effect from its use, and has used it when the condition of the conjunctival sac would seem to contraindicate it. It is decidedly preferable to the Saemisch operation, which only relieves the tension at the expense of a new traumatism; the evacuation of the hypopyon being not essential, since its absorption is assured under proper treatment. The cautery at a red heat should be applied to the underlying edges of the ulcer, and in case of onyx penetrate it deeply, experience having taught him that the floor of the ulcer will undergo resolution with a thorough cleansing, or slight curettement. The cautery is a direct, immediate stimulant, and destroys the microbic area with which it comes in contact, instead of creating a new condition favorable for infection, as the Saemisch operation does.

All of these cases need atropine, hot water, and the systematic influence of mercury. The latter may be accomplished by any method consistent with scientific medicine. Lagrange and Formaget have employed mercuric cyanide by conjunctival injection in the treatment of panophthalmitis, Chavelereau in the treatment of vitreous opacities, and Dunn in hypopyon keratitis. E. H. Bernst prefers mercuric cyanide to bichloride, claiming for it a quicker and more complete absorption. He is in favor of the method. De Schweinitz, Baker and Ray concur in his opinion, while Stirling, Reynolds and Savage have had unfavorable experience with this method. Fernandez reports encouraging results in the treatment of trachoma by the subconjunctival injection of the permanganate of potassium. An injection of one-per-cent. solution of cocaine is first given, fol-

lowed in about twenty minutes by an injection of from one-half to one gramme of a 1:1000 strength solution of permanganate of potassium. The eyes are washed daily with an antiseptic solution, and in about eight days (or after the swelling has subsided) the injection is repeated. Mellinger and Bossaline introduced India ink beneath the conjunctiva of rabbits, and demonstrated beyond cavil that fluids so introduced follow the greater lymph channels and surround the entire globe; the amount of ink actually entering the eyeball being small in comparison to the amount injected. They believe that the fluids also connect with the suprachoidal and intervaginal spaces of the optic nerve.

Abadie repeats his injunctions against bichloride solutions, especially when iodoform is used contemporaneously in purulent ophthalmia, on account of the evil effects on the cornea. Galezowski has abandoned the method, and Ray feels that he cannot depend on it exclusively.

The progress of medicine is not so much dependent on new discoveries as it is on the careful sifting of the evidence at hand and the elimination of its errors. Its gain has been one of principle at the expense of superstition, and to-day it is an exact science. The theory of subconjunctival injections must be an error, since it is incompatible with the first teachings of not only hypodermic medication, but all medicine. Mellinger and Bossalino's illustrated experiments, showing a section of an enucleated eye, in which India ink had been injected during life, and which shows the ink in the eye and surroundings, is interesting only because it shows the channels traversed, for it has no bearing on the efficacy of the method. That it was found in the eye and optic sheath should not occasion so much surprise as its absence in these parts would, since we know that were it not an inert, insoluble product, it would be found in every organ of the body.

Hypodermic medication is too well established, too frequently used, and the effect too palpable to doubt its immediate penetration of every organ of the body. It was for this that it was adapted and adopted. Its earliest promoter, Ruppaner, makes no claim in his treatise for especial benefit of the tissues at the site of injection. On the contrary, he speaks of the possibility of abscess in that region. We know that there is a disturbance of the relation of the cellular tissues at this point; that the solution injected is an

irritant; that the traumatism causes an increased leucocytosis—which are all favorable to the production of abscess even in a healthy tissue. Photophobia, lachrimation, congestion and pain are the predominant symptoms in corneal ulcer. The congestion is in direct ratio to the virulency of the infection. If this be great, the congestion in all the orbital tissue is great. There is no clinical data, no evidence, no law in medicine, that teaches us to select an already congested area for the introduction of an irritant, thereby accentuating the conditions instead of benefiting them. Conclusions are:

That the *rationale* of the treatment of corneal ulcers by subconjunctival injections is extremely questionable.

That the results are no better than if the injection be given in another part of the body.

That the eye not injected receives as much medication as the injected one.

That it accentuates already abnormal existing conditions.

That it adds a new traumatism to an old inflammation.

That it has a tendency to promote suppuration, to say nothing of thrombi.

---

#### EXPERIMENTAL RESEARCHES ON THE EFFECTS OF DIFFERENT ANESTHETICS.

This important subject has again been taken up by THOMAS and KEMP in the *Medical Record* of September 3, 1898. They tell us that as regards ether, it would appear that this agent produces a special contraction of the renal arterioles, with a constant damaging effect upon the renal secretory cells, similar to those which follow clamping the renal artery. The kidney shrinks in bulk, with consequent fall of the oncometric tracing, and accompanied by a diminution of secretion, marked albuminuria, and finally suppression. As remarked before, this condition of the kidney is not due to any change in the general arterial circulation.

These facts would seem to contraindicate the use of ether as an anesthetic when renal disease is present, and particularly when with albuminuria there is a tendency to pulmonary edema.

The effect of chloroform upon the kidney seems to be *nil*. The oncometric curves are nearly normal and are affected only through sharing in general circulatory changes. The secretion of urine continues up to the last

moment of life, and the albuminuria is so slight that its presence at all is apparently due only to respiratory interference. Meantime the action of chloroform on the heart, as shown by the carotid tracings, is directly depressing. Ether, on the other hand, shows evidence of cardiac stimulation throughout.

The A. C. E. mixture shows the special effects both of ether on the kidneys and of chloroform on the heart, either being predominant according to the mode of the administration. If a large percentage of air be simultaneously inhaled, as is the case when chloroform alone is administered, the effect is that of chloroform cardiac depression without the effect of ether upon the kidney. If, however, the A. C. E. mixture be administered more as ether is when used alone, then a study of the carotid and kidney tracings shows clearly that we have both the cardiac depression of chloroform and the renal derangement of ether combined. This seemed to cause such powerful effects upon the breathing and upon the heart that artificial respiration had to be resorted to in every dog to which this mixture was freely administered, which was not the case with either ether or chloroform. As far as the author's observations go, therefore, they fail to see any advantage in this mixture of chloroform and ether, but rather the reverse.

These objections appear to be still more applicable to Schleich's anesthetic. The cardiac depression of chloroform and the renal disturbance of ether are simultaneously developed in the tracings, similar to but to a greater degree than with the A. C. E. mixture. Schleich claims that mixtures of different anesthetics of different boiling—*i.e.*, maximum evaporation—points are safer than the administration of the anesthetic alone, on the assumption that the absorption of an anesthetic as to quantity depends upon its boiling point. The more volatile an anesthetic is, the less will be absorbed into the blood in a given time. Hence ether, the boiling point of which is 93° F., will not be absorbed so rapidly as chloroform, whose boiling point is 143° F. If, therefore, an anesthetic could be produced whose boiling point was the same as the normal temperature of the blood, the exact amount absorbed with each inspiration would be eliminated by each expiration. By causing the mixture to be at different degrees above this point, he claims that we can regulate at will the excess which the expiration would not remove, and thus the amount of the anesthetic

retained in the blood. His addition of petroleum ether or benzine to sulphuric ether and chloroform was further to facilitate the formation of a mixture or solution of anesthetics which would afford a safer means of absorption.

The authors believe that practically this reasoning is fallacious, because it assumes that these mixtures or solutions constitute a new chemical homogeneous compound which will always be inhaled as one substance in definite chemical proportions, just as a compound salt is one substance when swallowed after solution in water; whereas the fact is that ether remains ether and chloroform stays chloroform during the inhalation, and the proportion of either which will be absorbed will depend upon the mode of administration, a tight cone allowing an amount of chloroform to be taken which would be extremely dangerous, while the free admixture with air would so lessen the absorption of ether that its specific effects would be proportionately lessened. Meantime the adoption of benzine is not the adoption of an anesthetic, for Dr. S. T. Meltzer, in a communication to the writers on his experiments upon rabbits with petroleum ether, by inhalation through mouth and nose, as well as through a tracheal cannula, says: "Petrol ether is not a narcotic. If a rabbit was put under deep anesthesia by ether, and then ether suspended and petrol ether administered, the lid reflex soon reappeared and the rabbit woke up. The inhalation of pure petrol ether alone soon brings out a distinct tetanus and opisthotonos, to which the animal soon succumbs if the inhalation be continued. If the inhalation be discontinued at the appearance of the convulsions, the animal survives the tetanus, but this is then followed by a distinct paresis of all the extremities. If ether is given with the petrol ether, the tetanus movements are suspended, but not so paralytic after-effects; the rabbit dies of paralysis of the respiratory muscles."

There is, moreover, a physical reason for doubting the manageability of mixed anesthetics, due to the fact that if two agents of different maximum points of evaporation be mixed together, the more volatile of them will increase the evaporation of the other, by carrying off more of the less volatile one than if the latter were vaporized by itself. Thus more chloroform would be inhaled if mixed with ether than if it were administered separately.

That Schleich's mixtures have been used

in a number of cases without dangerous effects is no evidence that they are safe, for the same may be said of chloroform and of ether the world over. Mixed anesthetics of any kind might be employed in hundreds of instances without unpleasant results, though actually they were more dangerous than unmixed agents, for with chloroform itself surgeons have published reports of ten thousand administrations of it without one serious accident.

*THE TREATMENT OF INOPERABLE SARCOMA WITH THE MIXED TOXINS OF ERYSIPELAS AND BACILLUS PRODIGIOSUS: ITS IMMEDIATE AND FINAL RESULTS IN ONE HUNDRED AND FORTY CASES.*

COLEY makes a further contribution to his study of this subject in the *Medical Record* of August 27, 1898. He has used the toxins in a number of cases after a primary operation, with the idea of lessening the chances of recurrence. Theoretically this use of the toxins has much to recommend it, but as yet the cases are too few in number to justify positive statements. A few weeks' treatment with moderate doses is free from risk, and is worthy of trial.

The preparation at present used differs in no way from that described in Coley's previous paper. It consists of the mixed, unfiltered toxins of the streptococcus of erysipelas and bacillus prodigiosus, grown together for two weeks and sterilized by heating to 58° C. In children and patients much reduced in strength it is better to use the filtered toxins. This preparation is much weaker than the unfiltered, the relative strength being about one to ten. However much difference of opinion there may be as to the part the bacillus prodigiosus plays in causing the disappearance of sarcoma, the fact remains that all of Coley's successes, as well as those of other surgeons, have been obtained with the combined toxins, and he is quite convinced that the process of degeneration of the tumor tissue is greatly increased by the addition of the prodigiosus.

Many opinions have been expressed as to the nature of the process by means of which a cure is effected in the successful cases. The opinion which has been most generally advanced—though resting on theoretical rather than practical knowledge—is that it is a simple necrosis or sloughing process, resembling that following the injection of any powerful escharotic, like carbolic acid. Consequently,

it has been regarded as an entirely local process. This is far from the truth. While in some cases of soft round-celled sarcoma the rapid breaking down of the tumor would lend support to this view, there are many cases that absolutely disprove its correctness. A number of cases of sarcoma have disappeared entirely by absorption, with no breaking down; and furthermore, in several cases the injections were made remote from the tumor. This proves the action to be systemic as well as local. The toxins in some way, acting probably through the blood-serum, cause a necrobiosis with fatty degeneration of the tumor cells, the breaking down and formation of the slough depending entirely upon the preponderance of the cellular elements over the intercellular or fibrous stroma. In the spindle-celled variety absorption without breaking down is the more common process, while in the round-celled type the reverse is true. Usually, when possible, it is better to give the injections locally; a much larger quantity can, however, be safely given subcutaneously than when injected into the tumor, and this is a point of much practical importance. A severe chill and rise of temperature to 105.5° F. have been known to follow the injection of one-half minim of the mixed, unfiltered toxins when made into a highly vascular sarcoma. The severity of the reaction depends largely upon the rapidity of absorption.

The rule should be to begin with a minimum dose—for example, one-half minim—and slowly increase daily until the desired reaction has been reached. If this rule be carefully observed, the element of danger is exceedingly small. Inasmuch as the dose depends largely upon the virulence of the cultures from which the toxins are prepared, and since it is extremely difficult to keep cultures of the same degree of virulence, the dose must vary within certain limits and can be determined in the individual case only by trial, the temperature furnishing the guide. The initial dose should never be larger than one-fourth to one-half minim; boiled water may be added for the proper dilution. The aim should be to give sufficient to produce a temperature of 101° to 103° F. In some of the successful cases not more than three or four chills were produced during the entire course of treatment, and frequently patients have steadily gained weight while under treatment. This controverts the statement of some writers that the treatment is exceedingly depressing and causes rapid emaciation.

This may be true if the doses are too large, but not when the treatment is judiciously carried out. Strychnine may cause speedy death or act as an excellent tonic, according to the amount administered.

The strictest precautions should always be taken to guard against infection, for the reason that a patient is unusually liable to infection from other germs while taking the toxins. The skin should be rendered aseptic and the needle be sterilized by being passed through an alcohol flame before and after using.

It is possible in most cases to tell within a comparatively short time whether or not the toxins are likely to be efficacious. If no improvement is noted at the end of three weeks, there will be little use in continuing the treatment. In many cases marked improvement is seen within a week after the first injection. If improvement occurs the treatment should be kept up until the tumor has disappeared or until it is evidently again increasing in size.

The question of the cumulative action of the toxins if the treatment be long continued is an important one. The toxins are rapidly eliminated, and that no harm is likely to result from prolonged treatment is evidenced by the following cases:

In one case the toxins were administered steadily two or three times a week for a period of two and one-quarter years; the patient gained ten pounds in weight and remained in perfect health the entire time. In a second case the treatment has been continued, with few intervals of rest, for a period of nearly four years, with no ill effects. The writer has personally had two deaths from the treatment, and he has known of six others in the hands of other surgeons.

Out of a total of 140 cases, eighty-four were round-celled; twenty-one spindle-celled; six mixed; nine melanotic; two chondro-sarcoma; six sarcoma, in which the clinical diagnosis was not confirmed by microscopical examination; twelve sarcoma, in which the type of cell was not stated, though the diagnosis of sarcoma was confirmed by microscopical examination. Of the eighty-four round-celled sarcomata, thirty-five were more or less improved; three disappeared entirely, one patient remaining well upwards of three years, one at present well one and one-half years, and the third well at the end of one year, since which time he was not traced. Of the twenty-one spindle-celled, ten disappeared and all the others showed marked

improvement. Of the six mixed-celled, three improved; two were unimproved; one disappeared, and the patient remained well for three and one-quarter years, at the end of which time there was a recurrence in the abdomen, which proved fatal after six months' time. Of the nine cases of melanotic sarcoma only two showed slight improvement, the remainder being unaffected by the treatment. One large chondro-sarcoma disappeared, recurred at the end of seven months, and finally proved fatal; the other was slightly improved. Of the twelve cases in which the type of cell was not known, six were improved, five unimproved, and one tumor disappeared. Of the six cases not confirmed by microscopical examination, two osteosarcomata disappeared, two improved, and two remained unimproved.

Well over three years, eight cases; well from one to three years, nine cases; well from six months to one year, four cases; recurred after having once disappeared, four cases—two of these patients died, two are still living in good health after further treatment.

From published reports and personal communications, the writer has been able to collect thirty-five cases of inoperable sarcoma in which the tumor completely or very nearly disappeared as a result of the treatment in the hands of other surgeons. In twenty-six of these cases the tumor entirely disappeared. Of the total number, ten were spindle-celled; eleven were round-celled (one giant-celled); one myxosarcoma; and one endothelial sarcoma. In ten cases no microscopical examination was made, though careful examination by a number of surgeons rendered the clinical diagnosis scarcely open to question. In the remaining cases the diagnosis of sarcoma was confirmed by microscopic examination, but type of cell not stated. In addition, in five of the nine cases there was a history of recurrence after operation. Of the thirty-four cases, nine are now well upward of three years; nine from one to three years; in six cases the disease recurred in other regions of the body at the disappearance of the primary growth. This latter fact alone—that the disease recurred elsewhere—is sufficient to establish the correctness of the original diagnosis of sarcoma.

A careful study of the writer's cases, as well as those thus far treated by other surgeons, justifies the following conclusions, which are in almost perfect accord with those recently published by Moullin:

1. A considerable number of inoperable

sarcomata, the correctness of the diagnosis of which is beyond question, have entirely disappeared under this method of treatment.

2. A large proportion of these cases have remained free from recurrence more than three years after treatment—the period which has generally been accepted as of sufficient length to justify their being regarded as permanent cures.

3. Different varieties of sarcoma differ widely as regards the manner in which they are acted upon by the toxins. The results thus far show the treatment to be most successful in the spindle-celled variety, one-half of the spindle-celled sarcomata so far treated having disappeared. Round-celled sarcomata yield less rapidly, although a certain number have been successfully treated. No case of melanotic sarcoma has, up to the present time, shown more than slight improvement.

4. The action of the toxins upon sarcoma must be regarded as a rapidly progressing necrobiosis with fatty degeneration. This action is not the result of inflammation, nor does it resemble the destructive action of a local escharotic, but it is rather specific in character, exerting a direct influence upon the tumor cells.

5. The specific action is further confirmed by the fact that several tumors have entirely disappeared when the injections were made subcutaneously remote from the tumor.

6. This method of treatment is attended with a certain amount of risk, unless certain precautions are taken. The chief dangers to be guarded against are: (1) collapse from too large a dose of the toxins or from injections into a very vascular tumor; (2) pyemia from insufficient precautions as regards asepsis, especially in cases in which there is a granulating or sloughing surface. (That the risks are small is shown by the fact that in upward of two hundred cases treated personally death was caused by the injections in but two, one of which was so nearly moribund that no treatment should have been begun.)

7. The use of small doses of the toxins for a short period after primary operation, as a prophylactic measure, theoretically has much to recommend it, and if proper precautions be observed the treatment should be practically free from risk.

The action of the toxins of erysipelas upon sarcoma, as shown by clinical results, is in strict accord with the known action of the living streptococcus of erysipelas; therefore the method has a perfectly logical and scientific basis.

#### ASEPSIS IN OPERATIONS.

QUENU (*Revue de Chirurgie*, March, 1898), in speaking of Mikulicz's use of gloves in operations, says that he has not seen in his practise the amount of suppuration in hernias that Mikulicz has. The ideal is that a surgeon who practises the major operations should not touch abscesses, or, at least, that he should never put his finger in pus; and in Quenu's clinique an assistant takes charge of all phlegmons and suppurations, and after a vaginal or rectal examination the infected finger is brushed and washed with alcohol and dipped in permanganate of potash, the bisulphite of soda, and then in alcohol. If there is any doubt about the sterility of the fingers after the usual washing, they are washed in a concentrated solution of permanganate of potash, then in bisulphite of soda, then in alcohol, followed by a solution of 1 in 1000 of perchloride, and tincture of iodine is then painted on the skin under the nails.—*Quarterly Medical Journal*, July, 1898.

#### HYSTERIA AND BRAIN TUMORS.

KRAUSS (*Buffalo Medical Journal*, August, 1898) in considering the differential diagnosis of these affections, of cardinal importance to the surgeon, calls attention to the fact that all cases of suspected brain tumor with hysterical manifestations must not be considered as having been absolutely organic because death has occurred, since it is a well known fact that a fatal termination may sometimes result from the different effects of hysteria, and it is quite a mistake to look upon the disease as always having a favorable prognosis, so far as life is concerned.

Fournier and Sollier have observed cases of spasm of the glottis in hysterical girls so severe that death ensued; also in hysterical angina pectoris, which is generally curable, yet Potain reported a case in which death took place and in which on post-mortem examination absolutely nothing was found.

Fournier and Sollier also refer to hysterical anorexia in which there is sometimes a fatal termination, and even should recourse be had to artificial feeding there seems to be no power of absorption. The wasting continues and the patient dies. They also refer to the danger of forcible feeding in such cases. One of their patients who presented a marked degree of anorexia expressed a wish for some cheese, and died the same evening that she ate it. The authors point out that sudden death

may occur after hysterical vomiting, and they give the notes of one such case, no lesion of any kind being found on post-mortem examination. Thus it will be seen that the utmost care is necessary in making the examination, and still greater care and caution in interpreting the meaning of the different symptoms. In a previous paper Krauss has called attention to three groups of symptoms occurring in tumors of the brain, viz., the early symptoms, the classical symptoms, and the decisive symptoms.

The early symptoms are similar to those met with in neurasthenia and hysteria, as headaches, incapacity for mental work, disordered digestion, nervous irritability, and a general malaise. The classical symptoms enumerated in the order of their importance are: (1) head pain; (2) optic neuritis; (3) mental apathy; (4) nausea and vomiting; and as a special localizing symptom to be added to this group must be included (5) paralysis. The decisive symptom, choked disc, is the only symptom which has never been observed in the varied symptomatology of hysteria, whereas all the early and classical symptoms have been frequently noted in functional diseases. It is therefore of extreme importance that this sign should be sought for, not only at the first examination, but at every subsequent examination until its presence is determined, or its absence along with continued improvement signifies a purely functional disturbance in the patient.

#### "RECURRENT" GONORRHEA.

VALENTINE (*Atlanta Medical and Surgical Journal*, September, 1898) presents the following *résumé*: In many a case apparently cured of gonorrhea a discharge suddenly appears weeks, occasionally months, after the last evidence of disease was observed. This happens sometimes after coitus, sometimes without; after a glass of beer, after transient erotic excitement, or without any apparent provocative cause. Unless one knows the patient well, such a case may tax the practitioner's faith, if he would not deem the recurrence a new infection.

Oftentimes, indeed, microscopic examination shows such a suddenly appearing discharge to be loaded with gonococci, grouped in the manner characteristic of recent infection. These microbes are sometimes also disseminated throughout the discharge, or they appear scattered only.

The principal causes of such a "recurrent"

gonorrhea are: Marital reinfection; infarction of crypts, glands, or follicles of the anterior urethra; chronic residual posterior gonorrheal urethritis; gonorrheal prostatitis; seminal vesiculitis. Any two or all of these causes may be united in one case.

Whatever the cause, irrigations may soon bring about their apparent cure. And the disappearance of all symptoms of disease may be so rapid as to cause the patient and the physician to deceive themselves into believing that a permanent cure has been effected. The young practitioner especially should be warned against taking even a succession of such cases into statistic consideration, unless in each case he has assured himself that the patient is free from the causes of recurrence. To briefly discuss them:

Under marital reinfection, the evidences of gonorrhea in a woman may be so slight as to be imperceptible. The hopelessness of obtaining a cure in a man who is continually exposed to marital reinfection is too evident for discussion.

Experience daily shows patients so far returned to apparent health that the urine is perfectly free even from granules. Months, years, may go by without any results from provocative cause. Then suddenly the urine, from constitutional causes, becoming irritant to the urethra, reawakens its susceptibility to the gonococci that remained quiescent within its crypts, glands, and follicles, and an apparently new gonorrhea springs up.

Chronic residual posterior gonorrhea is the cause of autoinfection most obscure, the most difficult to diagnose, but not very difficult to treat. Its precise differentiation requires, however, something beyond ordinary experience in urethroscopy, and therefore is more proper for discussion in a paper written for specialists in genito-urinary diseases.

Roughly, though, it may be said that when the first morning urine is free from even granules, expression of the posterior urethra may detach sufficient flakes to be carried in the first urine. This, centrifugalized and examined microscopically, may reveal gonococci, of which no suspicion could be otherwise obtained.

The technique of expression of the posterior urethra is simple enough for even a tyro to perform. It in no wise differs from massage of the prostate and stripping the seminal vesicles, except that to obtain certainty regarding the location of the affection pressure upon the prostate and vesicles must be avoided.

In a brilliant paper on the subject of gonorrheal prostatitis Wossidlo, of Berlin, urges that no case of gonorrhea should be dismissed without assurance being obtained that the prostate is free from disease. Perhaps the majority of cases of "recurrent" gonorrhea are due to prostatic invasion.

Seminal vesiculitis, if gonorrheal, as it is in the majority of cases, may be the cause of recurrent clap. Its other symptoms, even more so than those of prostatitis, supply that vast array of manifestations so often diagnosed as neurasthenia.

If, in a case of recurrent gonorrhea, marital reinfection can be excluded by (a) examination of the woman; (b) infarction of the crypts, glands and follicles by urethroscopy; (c) chronic residual posterior gonorrheal urethritis by expression of the posterior urethra and posterior urethroscopy; (d) gonorrheal prostatitis by massage of the prostate, —then we must look for gonorrheal vesiculitis.

The local manifestations of the last three conditions are grossly the same, differing only in detail.

For such an examination the author deems it best to place the patient on a sofa, lying on his back. The apex of the index-finger and the bed of the nail being tightly packed with soap and then thickly anointed with vaselin, the finger is gently inserted into the rectum. The other hand rests above the pubis to steady and press down the pelvic viscera. The pulp of the finger is turned toward the front of the patient, and lightly outlines the prostate, but exercises not even the slightest pressure on any part of it. If the operator desires to elicit evidence of chronic residual posterior gonorrhea, he lets the finger glide from the prostate and exercises pressure, with increasing force, in a stroking motion forward from the lowermost margin of the prostate, endeavoring with each stroke to force the posterior urethra against the posterior aspect of the pubis.

The patient is then ordered to urinate, and if this is the region affected, the urine will contain flakes, perhaps even filaments or shreds, which the urinary stream was unable to detach. Microscopy of these products of massage will reveal the character, probably gonorrheal, of the posterior urethritis. If this results negatively, examination for prostatitis may be made in the same manner, several days later. The size, shape and hardness or softness of each lobe, as well as of the isthmus, should be ascertained; lobula-

tion or smoothness should be elicited, depressible points located, and the prostatic juice, if any exudes from the meatus, microscopically examined. If none escapes, the first urine the patient passes after this massage of the prostate should be centrifugalized for examination. If the prostate contains gonococci, they will be found either in the discharge that escapes from the meatus or flows into the posterior urethra or bladder and is carried off by the urine.

If the prostate is found to be normal, then the patient should be examined two or three days later for seminal vesiculitis. This is done in the same manner, except that the finger is passed up the rectum further, beyond the prostate and to its sides. In health the seminal vesicles can be barely, if at all, felt. When enlarged by disease they assume the shape of more or less tensely filled little sausages. In engaging the finger as high up as possible on these bodies, by curving the finger downward and toward the center with increasing force, the seminal vesicles may be stripped of their contents. These are treated in the manner as described under the examination for prostatitis.

The first of either of these examinations is usually attended with some pain, but the relief the patient experiences is usually so great that he will ask for its repetition.

As in all other genito-urinary work, gentleness in these manipulations cannot be too strictly followed. Nothing is gained by violence, even harm can be done. Physicians unable to devote the most exquisite gentleness and sympathy to these cases would do well to relegate them to others.

The treatment of recurrent gonorrhea should be directed to its cause, or perhaps better, its location.

Where marital reinfection is the cause, attempts to cure the husband must prove futile while the wife remains ill, as in the majority of instances prohibitions regarding coitus are of no avail.

Where the crypts, glands or follicles of the anterior urethra harbor gonococci, if systematic dilatations and irrigations do not entirely suffice, electrolysis will complete the cure.

When posterior urethritis, prostatitis or seminal vesiculitis causes the exacerbations of autoinfection, Kollman's posterior dilator, massage of the prostate and stripping of the vesicles will be required. Irrigations, as elsewhere described, will be found valuable adjuvants to the treatment. While it is not at

all likely that even the most copious irrigations will wash away enough of the *materies morbida* to materially affect the disease, they procure an artificial edema which renders the mucous membrane an unfavorable culture medium for the gonococci.

In all cases the general condition, as well as the nervous system, suffers deterioration. This must be met by constitutional treatment, tonics, baths, attention to digestion, indeed every means at our command to fortify the patient's resistance against further inroads of the disease.

---

*OBSERVATIONS ON GASTRO-ENTEROSTOMY AT THE Breslau CLINIC.*

Although the operation of gastro-enterostomy has now been practised over fifteen years, and, according to the author's research ("Statistical and Experimental Studies on Gastro-Enterostomy," by Dr. V. Chlumsky (Breslau), *Beiträge zur Klinischen Chirurgie*, Bd. xx, H. 1 and 2), there are over 600 cases on record, its results are not entirely satisfactory. The chief drawback has been found to be the establishment of a "*circulus vitiosus*," and most of the modifications of the original Wölfler operation have been undertaken for its correction. The writer's studies have been specially directed toward this particular phase of the operation, and are based on the consideration of the seventy-four cases in Professor Mikulicz's clinic, the recorded cases in the medical literature, and supplemented by experiments on animals and on the cadaver.

Of the seventy-four cases occurring in the Breslau clinic (1884-97) there were twenty-four deaths—thirty-two per cent. The operation was performed sixty-one times for the relief of malignant disease. Cause of death: collapse, thirteen; kinking and spur-formation of intestine, six; peritonitis, inhalation pneumonia, inanition and myasthenia contributed to the fatal result in the remaining cases.

Perfect healing without any intercurrent disturbances occurred only twenty-seven times. The greatest prolongation of life in cancer cases was two and one-quarter years and two and one-sixth years (still alive). All ten of the cases of operation for non-malignant disease are alive—one ten and one-half years after operation.

The first four operations were according to Wölfler's method. From 1891 to 1896

von Hacker's method alone was used, except for three cases of carcinoma. In all there have been thirteen operations by Wölfler's method, with five deaths; von Hacker's operation, forty-three times, with fourteen deaths. The relatively frequent mishaps attending von Hacker's method, especially the kinking and spur-formation experienced in the recent cases, led to a renewed trial of the Wölfler operation and to the development of a special procedure, employed eleven times, with five deaths. Five recent cases of anterior anastomosis with the aid of the Murphy button all recovered.

Considering the disturbances that follow gastro-enterostomy and the means devised to remedy them, we find that the following facts are brought out:

Wölfler's original operation (1881)—simple incision of the stomach and intestine—was apt to be followed by persistent vomiting. This dangerous symptom was, however, frequently observed in all the modifications of the original method. The vomiting, aside from that due to the anesthetic and to the irritation of the peritoneum by chemicals, may occasionally be due to a rotation or constriction of the intestine at its point of attachment. In the majority of cases the vomited matter is not fecal, but purely bilious, and the patient dies of inanition. An autopsy will show a dilatation of the stomach and of the proximal portion of the anastomosed loop, while the collapsed condition of the distal loop shows plainly that no food has reached it, the entire stomach contents having gotten into the wrong limb of the loop, and becoming stagnant there are finally pressed back into the stomach, causing incessant vomiting. Besides the intestinal contents bile is also forced into the stomach. If, however, the opening is made in such a manner that the gastric contents pass equally well into both limbs of the loop, matters soon regulate themselves, the proximal portion becoming narrower and the distal end dilated; the resulting intestinal spur will press more and more against the afferent or proximal portion.

In most of the cases the contents of the stomach became stagnant, notwithstanding the existence of active contractions. This result may be due to a marked contraction of the opening from an unusual degree of union and shrinking of the borders of the fistula; or the longitudinal fibers of the stomach, having suffered but little damage by the incision, contract the opening by

muscular action. The spur between the two intestinal loops may act as a wedge and block the gastric opening.

In a large proportion of cases it will be found that the stomach and the proximal loop are enormously dilated, the distal collapsed. In this condition the peristalsis of the first portion of the bowel has been sufficient to force out the incoming material, and has become dilated to the point of absolute stasis. In the cases that recover—and a few do—even after these ominous manifestations, the patient's strength has been sufficiently maintained to allow the intestines to respond with further peristalsis, driving out the contents of the loop along into its proper channel. Another cause is to be found in the dissimilar size of the gastric and intestinal openings, although these were originally made of an equal length, but the intestinal wall gives less, and the stitches are, consequently, inserted farther apart, resulting in considerable puckering, which may block the opening.

The chief cause of vomiting is generally attributed to the entrance of bile and pancreatic secretions into the stomach. To prevent this occurrence Wölfler proposed fastening the two viscera together so that their axis of peristalsis should be directed the same way; this improvement, however, failed to accomplish its end. Further modifications were devised. Wölfler, Czerny, Mikulicz, and many others, endeavored to narrow the orifice of the proximal loop. If this attempt was only slight, the gastric contents were not prevented from passing in; if the opening was rendered very narrow, an accumulation of bile and pancreatic juice took place, causing vomiting and symptoms similar to those of incarceration.

In 1890 Lauenstein recommended making an anastomosis between the proximal loop and another coil. A better suggestion was that of Jaboulay and Braun, of establishing a communication between the proximal and distal loops. The merits of this procedure soon became obvious, but it had the disadvantage of prolonging the operation, and certain operators (among them Braun) only employed it as a secondary measure to relieve intractable vomiting. This measure saved four of Mikulicz's patients from an apparently certain death.

Kocher, Doyen, Chaput and others sought to give the opening the character of a valve. Kocher's method has as yet not been much practised. Doyen's, while extremely com-

plicated, has given its deviser excellent results. In either method the main principle of the operation is contained in the position of the attacked intestine, Doyen putting the proximal above the distal, Kocher the distal in front of the proximal loop. Hahn and others thought to diminish the dangers of spur-formation and the flow of bile and pancreatic juice into the stomach by making only small openings; the result was bad, as these orifices became greatly reduced in size. The reverse condition—large openings ten to fifteen centimeters long, as recommended by Stansfield and Senn—was not productive of any special advantage. The operation is longer, the danger of infection is increased, a spur may form, and notwithstanding its size, the fistula may become obliterated.

Division of the gut, implantation of the distal end into the stomach and of the proximal into the distal segment below the site of anastomosis, was recommended by Wölfler and Chaput, but it is questionable whether even this procedure succeeds in keeping the bile from reaching the stomach.

Attempts have also been made to remedy some of the other unfavorable features of gastro-enterostomy. The loop of bowel selected for attachment varied greatly—from the lower end of the ileum to that portion of the jejunum immediately succeeding the duodenum. Rockwitz used Nothnagel's suggestion of determining the direction of the intestine by causing peristalsis with the application of salt to the bowel. The fallaciousness of this test was soon revealed.

In order to avoid the occurrence of a fatal peritonitis, so frequently observed in all methods of operation, numerous procedures not requiring the immediate opening of the stomach and intestines were tried—application of chemicals to the mucous membrane, ligation causing sloughing of tissues, etc. These methods have not been found to present any improvements over those already known.

In 1887 Senn, with his bone plates, was the first to employ a new method, which sought more quickly and surely to establish an anastomotic opening. Numerous other devices based on the foregoing principle quickly followed. Of these the Murphy button is the only one that has stood the test of time. It possesses the following advantages: The operation is materially shortened, the opening is ideal in its working, the danger of infection is much diminished, the passage of the stomach contents outward is more quickly and easily obtained, and spur-forma-

tion is prevented. Its disadvantages are its size—it either is so large that it fails to pass out of the stomach, or it is so small that the opening is insufficient; it may not be passed out and thereby produce unpleasant complications; its results as regards mortality are scarcely any better than with the suture method. The use of the button should be limited to cases of malignant disease.

The chief cause of death after gastro-enterostomy is "collapse." Improvement in this direction, according to Czerny, must be sought for by a more judicious selection of cases; according to the author, in perfection of technique.

With regard to the various modifications of the original method, von Hacker's is only an improvement of Courvoisier's operation. This "posterior" gastro-enterostomy has been much employed in recent years, and gives comparatively better results than the Wölfler operation. This advantage, however, may be only apparent, owing to the prevailing tendency to employ the simple anterior operation on the more desperate cases. Von Hacker's original contention that his method did away with the entrance of intestinal contents into the stomach has not been verified. The operation does not possess any essential advantages, and is attended with certain drawbacks less marked or wanting in the other methods.—*Annals of Surgery*, August, 1898.

ON CARDIAC FAILURE AND ITS TREATMENT. With Especial Reference to the Use of Baths and Exercises. By Alexander Morison, M.D. Ed.

London: The Rebman Publishing Company, L<sup>td</sup>., 1897.

Although this book has but recently been received for review it appeared, as its title-page states, in 1897. As is indicated in its title it deals with the remedial measures other than drugs which are believed to be of value in cardiac disease. The volume opens with a review of our knowledge of the physiology of the heart in order that the reader may grasp the fundamental facts upon which the author bases his deductions. This portion is dealt with in a very useful manner in that the scientific side of the question is closely linked with the practical. All this text is included under the general heading of the Diagnosis and Symptomatology of Cardiac Failure. The second part of the volume discusses the

Neuro-muscular and Hæmic Factors in Disease of the Heart and Their Bearing upon Prognosis and Treatment. Part III deals with the General Treatment of Cardiac Failure, and Part IV its Treatment by Baths and Exercises. This part is by far the most exhaustive portion of the work and covers more than one hundred pages.

It is difficult to review a monograph designed to elucidate the views of an author, for he is supposed by the very nature of things to put forward his own peculiar ideas. In this work Dr. Morison makes himself a special pleader for balneological methods, with special final reference to Nauheim in a chapter by Dr. Groedel.

There is no doubt that such methods do great good in a certain proportion of cases, and the men who know the bath methods are the first to recognize the fact that like all other therapeutic methods they will not do all cases good. This is an important fact for the general practitioner to recall before sending his patients to Bad Nauheim and elsewhere, and this book will give him clear ideas as to the rules which should govern his advice.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Edited by De Forest Willard, A.M., M.D., Ph.D.

Philadelphia: William J. Dornan, 1898.

This book, in addition to a list of the members of the Association and a record of the transactions, gives the papers presented by the members at the last regular meeting. The book contains an admirable picture of the late D. Hayes Agnew, and a careful report of the discussion on some extremely interesting papers.

A TEXT-BOOK OF MATERIA MEDICA, THERAPEUTICS, AND PHARMACOLOGY. By George Frank Butler, Ph.G., M.D. Second Edition.

Philadelphia: W. B. Saunders, 1898.

This book, the first edition of which we reviewed in the THERAPEUTIC GAZETTE some time ago, now amounts to nearly 900 pages and deals with drugs according to a classification which is peculiar to its author and which has, we think, quite as many objections to be raised against it as some of the other classifications which its predecessors have attempted.

The early part of the work deals with a general consideration of pharmacology and therapeutics, with pharmaceutical preparations, then with what are known as "disease medicines," "symptom medicines," and

"topical remedies." As we have said before, there are necessarily many drugs which are used to relieve symptoms which are also used to relieve disease, and *vice versa*. Thus expectorants are classed among symptom remedies, while restoratives are classed among disease remedies.

On glancing over its pages we find that although nitrohydrochloric acid is mentioned as a pharmaceutical product, nothing is said about its therapeutics. Under the consideration of Animal Extracts we are told that "heart extract has been recommended in cases of nervous prostration, it being claimed that its action tends to raise the blood-pressure and increase the number of blood-corpuscles." This seems a rather indirect employment of a substance which, if it possesses any property at all, we should suppose would be employed in cardiac affections rather than in nervous prostration.

Under Mercury it is stated that should tonic doses be continued for too long a period there will be an increased weight owing to too great stimulation of the lymphatic system. This is not what is usually taught. On the contrary, it is generally stated that wasting follows the use of excessive amounts of mercurials. Under the article upon Antipyretics the following statement occurs which we fail to understand: "When the body is in a state of hyperpyrexia the heat center is in a depressed condition owing to certain poisons circulating in the blood, and will not respond to the normal limit of body temperature. Acetanilid increases the irritability of the heat center, causing it to respond to a lower temperature, and through its action on the vasomotor center stimulates the vasodilators, thereby augmenting the peripheral circulation, with consequent increase of heat dissipation." What this means from a physiological standpoint we do not know.

In the chapter upon Anesthetics, under the treatment of Untoward Manifestations it is recommended that one electrode be placed upon the larynx and the other one upon the epigastrium. Nothing is said as to the character of the electricity which should be used nor of the dangers of these applications, not to speak of their futility. Only thirteen lines are given to the consideration of nitrous oxide, and therefore it has been impossible for the author to give sufficient directions as to how it shall be employed. The prescription on page 418 is taken in every detail, even as to quantities, from another book on Therapeutics, save that in this instance the

quantities are only given in apothecaries', whereas in the book quoted from both the metric and apothecary systems are given.

The description of the effects of digitalis upon the circulatory system is not clear from a physiological standpoint and somewhat contradictory. On page 544 the following statements occur: "It is asserted that the action of digitalis may be manifested for some time upon discontinuance of a brief dosage. With regard to the specific effect of the drug upon the heart muscle this is not true, since the influence of the drug lasts but a few days indirectly through the additional muscle power developed during a few weeks' administration." Exactly what this means we do not know. It is then stated that in cases of vascular tension digitalis should be combined with a vasodilator, of which opium or morphine is generally the most useful. We would suppose that nitroglycerin was *facile princeps* the remedy in such a case. Then, too, it is stated that digitalis is recommended by all authors in every valvular disease of the heart with the possible exception of aortic regurgitation, but nothing is said of the fact that digitalis is not needed in the presence of any valvular lesion unless there is failure of compensation. We doubt very much whether it can be proved that manna is a cholagogue, as stated on page 671, and the statement that aloes has no local action is doubtful. Further than this, the statement that aloes if used habitually may bring on rather grave hemorrhoids is hardly in keeping with another which immediately follows, to the effect that the principal use of aloes is as a purgative for habitual constipation; and again, after calling attention to the secondary astringent influence of rhubarb, it is stated that this drug is a valuable remedy as a simple laxative for children. We are told that the infusion, compound licorice powder, syrup and confection of senna are employed, but nothing is said about the fluid extract of this drug. Under the heading of croton oil it is stated that in lead colic this oil is probably superior to all other purgatives, which, while not absolutely incorrect, is a very broad statement which needs qualification.

The second edition has been improved by an article on the Untoward Effects of Drugs, which has taken the place of the previous one upon Definitions, and this article is accompanied by an exhaustively arranged table designed to elucidate the facts therein stated.

At the close of his preface the author earnestly requests any reader who may dis-

cover an error of whatsoever character to report the same to him promptly.

It is said that books to a large extent reflect the image of their author, or at least give an idea as to his personal characteristics. It is evident from this book that Dr. Butler possesses two great attributes of success—one is the ability to do a large amount of work, and another is to bring together many interesting facts. The fact that the book has reached a second edition within a comparatively short space of time indicates that his labors have been appreciated.

**TREATISE ON THE SCIENCE AND PRACTICE OF MIDWIFERY.** By W. S. Playfair, M.D., LL.D., F.R.C.P. Seventh American from the Ninth English Edition. Copiously illustrated. Philadelphia and New York: Lea Brothers & Company, 1898.

It is now five years since the last English edition of this book appeared, and during that time the science of obstetrics has advanced with very extraordinary speed, and has at the same time broadened materially. It therefore became necessary for the author to thoroughly revise the present edition and to call to his aid a number of younger men, whose deft touches can be found in many portions of the work. The chapter upon Conception and Generation has been revised by Dr. Eden, a number of the illustrations have been taken from Crookshank's Bacteriology, and the proofs have been largely gone over by the cousin of the author, Dr. Hugh Playfair. These statements convey to the reader a clear idea of what Playfair's Obstetrics is in its seventh American edition. It has always been one of the most important works upon this subject, and it is to-day the text-book in many of the greatest and best schools in this country and England. Unlike other books revised by an author advanced in years, its text has been kept very well in touch with the advances which have been made.

**A MANUAL OF THE DISEASES OF CHILDREN.** By John Madison Taylor, A.M., M.D., and William H. Wells, M.D. Illustrated. Philadelphia: P. Blakiston, Son & Co., 1898.

When we look at the preface of this volume we meet at first glance with what seems to us to be a contradictory statement, for we are told that the authors do not claim this book to be a treatise on the maladies of childhood, but that their aim has been to present in a clear and concise manner the chief points in the description, differentiation and treatment of the diseases of childhood! We are told

that the authors do not attempt to offer much that is original or novel, and only obtrude their individual views when commenting upon the opinions of the great masters in the field of pediatric medicine!

There are twenty chapters in the book, beginning with the Physiology of the Infant and Child, proceeding to the diseases occurring at or near birth, and giving directions as to the care of infants and children. Chapter V is devoted to a discussion of the breeds of cows best adapted to infant feeding. After this is a chapter limited to artificial diets and recipes, and then follow those upon the diseases of the various organs, closing with others on the infectious diseases. The last two chapters are devoted to general considerations in regard to physical development and disease, and accidents requiring surgical procedures, which last is rather an innovation in a volume of this character.

It seems to us to be rather a mistake to have introduced a chapter upon Bubonic Plague, in view of the fact that the book is not supposed to discuss all the maladies of children.

An advantage gained by the reader of this volume is the fact that its authors have seen a large number of sick children through long connection with public institutions, and therefore the practical advice which they give is in many cases the result of adequate personal experience.

**A MANUAL OF PHYSICAL DIAGNOSIS.** For the Use of Students and Physicians. By James Tyson, M.D. Third Edition, revised and illustrated. Philadelphia: P. Blakiston, Son & Co., 1898.

This is another one of the small octavo volumes which have been recently published dealing with physical diagnosis. It covers less than 300 pages and is evidently the outcome of Dr. Tyson's personal experience in teaching this important portion of medical learning. In other words, it contains just what the student needs without many additional facts, which, burdening his mind, would prevent him from remembering the main points which are of vital importance in the practical application of this subject. The illustrations showing the different forms of the malarial organisms are taken from Dr. Tyson's book upon Practice of Medicine.

This edition of Dr. Tyson's "Physical Diagnosis" deserves success and will doubtless receive the approbation which has been meted out to its predecessors and to his other contributions to medical literature. The price of the book is \$1.50.

**BRAITHWAITE'S RETROSPECT OF MEDICINE.** Simpkin, Marshall, Hamilton, Kent & Company, Limited, London, 1898. January to June.

We have so often referred with words of praise to this very useful retrospect, or synopsis of current medical literature, that we need only remind our readers that another valuable volume covering the first six months of 1898 has issued from the press and that it in every way maintains the reputation already made by its predecessors.

**TEXT-BOOK UPON THE PATHOGENIC BACTERIA.** For Students of Medicine and Physicians. By Joseph McFarland, M.D. Second Edition, revised and enlarged. Illustrated.

Philadelphia: W. B. Saunders, 1898.

In the present edition we are told that chapters have been added dealing with the bacteriology of whooping-cough, mumps, yellow fever, hog-cholera and swine-plague, others describing the methods of determining antiseptics and germicides, of determining the thermal death point, and describing the gas-producing bacillus and the proteus vulgaris. One of the first things that strikes us is the fact that the type and the paper of this manual is much better for the eye than that which is found in some of its contemporaries, although it does not seem to us that all of the micro photographs are as useful in depicting what the author wishes to show as they might be. Nevertheless, as a means of bringing the student and physician in touch with the general points of bacteriology as they should be known to-day by the well informed medical man it seems to us that this volume fulfils its objects admirably.

**TROPICAL DISEASES.** A Manual of the Diseases of Warm Climates. By Patrick Manson, M.D., LL.D. (Aberd.). With 88 illustrations and two colored plates.

New York: William Wood & Company, 1898.

Dr. Manson's reputation as a student of tropical diseases is advancing with strides which are noteworthy, and he is bringing forward this important topic as a field of medical study in a manner which deserves great praise and which is receiving recognition not only in his own country but abroad. He is doing great good to medicine not only as a science, but to many persons in military and civil life who would otherwise be doomed to illness or death through lack of proper knowledge of the prophylaxis and treatment of maladies as they occur in hot countries. His small octavo volume is divided into sections dealing with Fevers and General Diseases of Undetermined Na-

ture, as Beriberi, Epidemic Dropsy and Sleeping Sickness, Abdominal Disease, Infective Granulomatous Diseases, Animal Parasites and Associated Diseases, Skin Diseases, and Diseases of an Uncertain Nature. Why there should be two separate sections dealing with "diseases of an undetermined nature" and those of an "uncertain nature" is not clear to us. Attractive portions of the volume are not only its dealings with the pathological aspect of the subjects discussed, but also with treatment, and as it is a manual written by one who is thoroughly in touch with his subject we doubt not that it will prove very popular. After one has looked over its illustrations a feeling of thankfulness arises that whatever diseases we may be exposed to in this temperate climate we at least escape some of the frightful maladies which Dr. Manson depicts so clearly.

**ENCYKLOPÄDIE DER THERAPIE.** Herausgegeben von Oscar Liebreich. Unter Mitwirkung von Martin Mendelsohn und Arthur Würzburg. Zweiter Band, III, Abtheilung.

Berlin: Verlag von August Hirschwald, 1898.

The present fasciculus extends from the middle of the article upon Hydronephrosis to that on Tumors of the Breast and covers a range of subjects which can only be considered therapeutic by accepting that term in its widest sense. The term therapeutic is, however, justified as it was in the previous fasciculi by the fact that the authors have endeavored to show how by a clear understanding of the disease these remedial measures may be properly undertaken. As in earlier volumes the authors will be recognized as being men who speak with authority. To those of our readers who can read German, we heartily commend this valuable encyclopedia.

**HAND-BOOK OF MATERIA MEDICA FOR TRAINED NURSES.** By John E. Groff, Ph.G.

Philadelphia: P. Blakiston, Son & Co., 1898.

This is a small octavo of a little over 200 pages, dealing with elementary facts in regard to Materia Medica, Pharmacy, Therapeutics, and Toxicology. From it the nurse is supposed to learn the official names of preparations, their doses, the symptoms produced by overdoses and the antidotes. A copious glossary arranged alphabetically reviews to a large extent the previous text in the book, and the chapters all end with a summary designed to fix in the mind what the pupil has learned, in question and answer form.

**A MANUAL OF OTOTOLOGY.** By Gorham Bacon, A.B., M.D. Illustrated. Philadelphia and New York: Lea Brothers & Company, 1898.

This is a small octavo volume of a little less than 400 pages, dealing with the principal facts in otology, freely illustrated when necessity for illustration exists, the pictures being taken from other works and from the experience of the author, and in addition a colored plate showing an abscess of the cerebellum following chronic suppurative otitis. Many pictures of instruments are included. The object of the author has been to present his text in such a way that it would prove of interest not only to the specialist, but to the general practitioner. Dr. Bacon believes that the general practitioner knows too little about and pays too little attention to diseases of the ear, not only for his own sake, but also because trouble in this organ is so frequently followed by serious lesions in the central nervous system.

**ELEMENTS OF HISTOLOGY.** By E. Klein, M.D., F.R.S., and J. S. Edkins, A.M., M.D. Copiously Illustrated. Revised and Enlarged Edition. Philadelphia and New York: Lea Brothers & Company, 1898.

This edition, which bears Dr. Klein's signature of 1898, keeps the text of this well known book upon histology closely in touch with the recent researches in this branch of medical study. The extraordinary advances which have been made in regard to the structure of the central nervous system and the sensory organs by Golgi, Cajal and others have made it necessary for a large part of the text to be revised, and most of this work has been done by the assistant author, Dr. Edkins. Many new illustrations have also been introduced. Unlike many books published in as condensed a form as this the illustrations are unusually good, and there is every reason to believe, because of the care taken upon its revision, that the volume will continue to have its popularity among teachers and students.

**A COMPEND OF DISEASES OF THE SKIN.** By Jay F. Schamberg, A.B., M.D. Freely illustrated. Philadelphia: P. Blakiston, Son & Company, 1898.

This book is a part of the quiz compend series, published by the Blakistons, which have been before the profession for so many years, and deals with the elementary facts in dermatology which it is necessary for the ordinary student to know, particularly in those schools where some knowledge of the specialties of medicine are required in those

who desire to graduate. A rather unusual characteristic of the volume is the fact that most of the illustrations seem to be taken from photographs of patients who have been directly under the author's care.

Considering the size of the book, ample attention is given to the subject of treatment.

**LABORATORY WORK AND PHYSIOLOGICAL CHEMISTRY.** By F. G. Novy, Sc.D., M.D. Second Edition, revised, enlarged, and illustrated. Ann Arbor: George Wahr, 1898.

This book is designed for directing laboratory work of medical students and in showing them how to study the physics and physiology of the digestive functions of the blood, the urine and other substances which the body contains normally, or which it speedily eliminates as effete material. The second edition has appeared within a very short time after the publication of the first. The first chapters deal with the fats, the carbohydrates and proteids. Then follow others upon the saliva, the gastric juice, the pancreatic secretion, the bile, blood, milk, and urine, while the closing chapter deals with a list of reagents.

While the book is manifestly designed for the use of Dr. Novy's own students, we doubt not that other teachers will find it a valuable aid in their work. At the close of the volume are a number of illustrations of the various sedimentary substances found in the urine, taken from the work of von Jaksch.

**A MANUAL OF CHEMISTRY.** By W. B. Simon, Ph.D., M.D. Sixth Edition, thoroughly revised. Illustrated with colored plates and engravings. Philadelphia and New York: Lea Brothers & Company, 1898.

That six editions of Dr. Simon's Chemistry should have been called for within the space of, comparatively speaking, a few years indicates that he has a knack of arranging chemical knowledge in a form which is easily assimilated and which will prove valuable to both teachers and students. To those who are unfamiliar with previous editions we may state that the book first deals with the fundamental properties of matter and with general questions of physics. Then non-metals and their combinations, and metals and their combinations, are discussed. Finally, the latter portion of the book is devoted to analytical chemistry with the consideration of carbon compounds and physiological chemistry. The very last pages are devoted to tables of weights, measures, and elements.

The colored plates, all of which have been prepared with the greatest possible care, as is evident from their neat arrangement, will prove exceedingly valuable to the student working in the laboratory, since by this means he can at once identify his reactions in a far easier way than if the color changes were simply described in words rather than pictured in colors. The portion of the book dealing with the newer chemical compounds, which are now used so frequently in medicine, is particularly interesting to the modern physician.

### LONDON LETTER.

BY RAYMOND CRAWFORD, M.A., M.D. OXON., M.R.C.P.  
LOND.

The summer holidays are now at an end, and the inaugural ceremonies at the various medical schools are in full swing. Charing Cross Hospital presents attractive fare to its novitiates in the form of a public lecture by Professor Virchow, who will afterwards be entertained at dinner by a distinguished medical company. To those who disparage the professional man of modern medical London it will come as a surprise that the lecture is far more in favor than the dinner—be it granted however that the lecture is free, and the dinner to be consumed only upon payment of a guinea. On the whole there is a remarkable absence of substantial changes to record in the hospitals themselves since this time a year ago. One noteworthy feature is the extensive building in connection with the London School of Medicine for Women, which has been necessitated by the very rapid growth in London of the movement for the education of women in the study of the healing art. A few years ago the medical woman was a mere object of detestation to her professional brothers, and only to be tolerated so long as her services were devoted to the dissemination of Christian knowledge, and not to the quest of commercial gain. Now all this is past, so far as London is concerned, although the same battle is being fought out successively in the provincial towns, and a fair livelihood is open to any competent medical woman.

Dr. Carstairs Douglas contributes some interesting notes to the *Glasgow Medical Journal* of a case of malignant disease treated by

nuclein. This therapeutic agent has not at present found much favor with the profession on this side of the Atlantic. Dr. Douglas employed nuclein in the hope of relieving the toxic cachexia, inferring the likelihood of its usefulness from the benefit obtained in other diseases in which toxemia is a prominent feature. The patient was a cachectic woman of thirty-eight, who had previously undergone vaginal hysterectomy for uterine cancer, and in whom a recurrence had shortly appeared in the right iliac fossa. Pain was great, but was mitigated by constant use of morphine; anemia and feebleness were extreme, and leucocytosis excessive, so that any benefit to be derived from the nuclein should have been due rather to some inherent chemical activity of the substance than to its alleged property of increasing the number of polynuclear leucocytes. The preparation employed was a five-per-cent. solution of pure nucleinic acid from yeast, supplied by Parke, Davis & Co., and was administered by the mouth. The solution was a brown liquid of strongly acid reaction, with the odor and taste of cresol, due to the preservative cresol it contained. A small teaspoonful was given three times a day, between meals, and well diluted. The chief clinical interest of the case centers in the condition of the urine, which was carefully noted both before and during the administration of the nuclein. In the first instance the daily urea excretion was 9.09 grammes, or less than one-third of the normal, while the uric acid excretion was 4.354 grammes—that is to say, nearly eight times the normal daily amount. Phosphoric acid was represented by a daily output of 5.21 grammes. The diminished urea output was probably due to the essentially non-nitrogenous diet, aided perhaps by secondary growths in the liver, which may have disturbed the urea-forming function of the liver. The uric acid excess and the increased phosphoric acid were no doubt derived, as Horbaczewski has shown, from the nuclei of the disintegrated leucocytes. After the nuclein had been administered for a fortnight, chemical examination of the urine showed a daily increase of uric acid to 4.876 grammes, while the urea and phosphoric acid remained at much the same level. It is a reasonable inference that the increased uric acid was derived from disintegration of the nuclein within the body. At first the patient seemed to derive some general betterment from the treatment, but it was at no time marked, and after a short time a steady de-

terioration set in and persisted until death. The administration of the drug by the mouth seemed to be quite free from ill effects, and at no time was there any gastric or other digestive disturbance assignable to the nuclein; nor was there any suggestion of gouty disturbance, a fact which points to defective elimination by the kidneys as a probable factor in inducing deposition of urates from a condition of uricacidemia.

One is often asked to recommend a health resort for a subject of gout or rheumatism. There is a deep-rooted insular prejudice in this country among the laity in favor of the seaside for convalescence from every ailment. Dr. Hobhouse has studied attentively the relation of the seashore to gout and rheumatism, and also the efficacy of salt baths in these conditions. The views he recently communicated on the subject to the British Balneological and Climatological Society are well worth consideration. He believes that sea air as such has little effect on rheumatic troubles apart from the question of dryness of the soil, the prevailing winds, the amount of precipitation and of sunshine, and the aspect of the place. Thus it becomes a question rather of the individual seaside resort, than between seaside and inland. In the autumn, when damp fogs prevail inland, speaking generally the seashore will be found drier and therefore more suitable; while in the spring, when east winds run riot, inland resorts will be less exposed to their influence than the seaside. For a winter resort for rheumatic subjects, a dry soil and one that absorbs moisture quickly is all-important. Such a soil is that of Egypt. It is easy to gauge the influence of any climate or locality on rheumatism, because rheumatic manifestations are almost invariably accompanied by pain, and therefore impress themselves on the subject.

The promoters of aspiring health resorts would do well to lay to heart Dr. Hobhouse's timely warning, that the reputation of a health resort is best maintained by a frank statement of the conditions for which it is unsuitable, as well as those it suits. The revilings of one patient who has been victimized do more harm than can be counterbalanced by the commendation of the many who may have reaped its benefits. Comparison of the statistics of acute and subacute rheumatism in Brighton, Hastings and Plymouth shows a percentage incidence almost identical with that of the large London hospitals; from which it would seem that the sea as such has

no special influence on these forms of rheumatism. Hobhouse summarizes his conclusion that marine climates are not indicated in the treatment of rheumatic affections, though patients in a weak and anemic condition, after acute and subacute attacks, often benefit greatly from the tonic influence of the air and do not tend to relapse. On the other hand, the health statistics of British seaside towns all point to the prevalence of chronic rheumatism. It is interesting to find the relation between the prevalence of acute and chronic rheumatism so distinctly negated. The prevalence of rheumatism at the seaside is a matter of supreme importance in England, where boys and girls from all parts of the country are congregated together in seaside schools. Dr. Hobhouse gives it as his experience that the slight and abarticular forms of rheumatism, which are so common in children, and so often unfortunately linked to disease of the endocardium, are benefited by seaside residence. With regard to gout, especially in its outspoken forms, nearly all physicians will agree with Dr. Hobhouse that those with any active symptoms are far better away from the sea altogether, and if they get an attack there, should get away as soon as possible afterwards.

It is perhaps open to question whether acute rheumatism is materially influenced by any other treatment than that which Nature herself imposes on the subject, viz., rest. Whether salicylates cut short an attack is still an open question, and even if their usefulness be conceded there are many that maintain the superior efficacy of the old combination of quinine and an alkali. But to Mr. John O'Connor has it been left to decide "that surgery is a curative agent in acute rheumatism, and that the sooner the latter term is dropped and acute infective arthritis substituted, the sooner shall we be in a position not only to better understand the complaint, but to more successfully combat it by prompt operative measures." These deductions, if we may trust the short notes communicated to the *Glasgow Medical Journal*, appear to be derived from two cases, in neither of which can we satisfy ourselves of the existence of acute articular rheumatism. To use a seeming paradox, acute rheumatism is essentially a chronic disease—that is to say, a patient in whom the disease has once manifested itself is always liable to recurrence. Mr. O'Connor does not tell us whether his drastic treatment prevents recurrence, or whether at each recurrence the operative measures are repeated.

### THREE RECENT CASES SHOWING NECESSITY FOR EARLY OPERATION IN INTESTINAL OBSTRUCTIONS.\*

BY JOHN B. ROBERTS, M.D.

Fatal delay in resorting to operative exploration in cases of supposed intestinal obstruction often comes to the knowledge of surgeons. This paper has been prepared for the purpose of calling attention to the value of prompt exploratory incision into the abdomen, a surgical procedure so free from

danger in competent surgical hands as to make very great the responsibility of relative, friend or doctor who encourages delay. Even in cases of doubtful diagnosis the danger of exploration is less than that of waiting.

CASE I.—Intestinal obstruction due to entanglement of small intestine in a congenital opening in the mesentery; recovery after celiotomy. A young man, aged nineteen, a patient of Dr. A. Stark, of Philadelphia, was seen on December 4, 1897, with a history of having had no evacuation from the bowels for five days. He had had a somewhat similar attack of obstinate constipation a year previously. He had pain in the abdomen, his temperature was about 101°, and his ab-

\*Read before the Philadelphia County Medical Society, Sept. 14, 1898.

domen was distended. The abdomen was opened in the middle line and the small intestine found distended and congested. In the ileocæcal region the small intestine was acutely bent and entangled in an opening in the mesentery. Without any great difficulty I was able to pull the intestine from the opening, and this allowed the caliber of the gut to be reestablished. There was no evidence of gangrene, but the intestine where it was acutely bent showed some plastic lymph in the angle of the flexure. There apparently was no actual protrusion of a loop through the opening, but the bent intestine was seemingly thrust into the orifice in such a way that the sharp bend closed the lumen. The intestine was incised at a point considerably above the seat of obstruction and a large quantity of gas and liquid feces permitted to escape. This opening was sutured in the usual way and the bowel dropped back into the abdomen. The abdominal wound was then closed.

The temperature of the patient stayed high for a few days, but convalescence was uneventful, except for a slight attack of delirium, the reason for which was not ascertained.

The administration of calomel and sodium phosphate was started four hours after the completion of the operation. This early resort to laxatives I consider a valuable adjunct in the treatment of peritonitis, as well as in operative cases where the continuance or occurrence of inflammation of the peritoneum is feared.

The orifice seemed, from its appearance, to be of congenital origin. If the patient's condition had been better, an attempt would have been made to close the mesenteric hole with a flap of omentum or peritoneum. As his pulse was 118 and his temperature 101° before operation, and there was evidence of peritonitis, it was thought best to add no risk by prolonging the operation.

CASE II.—Intestinal obstruction from constriction of portion of bowel at internal inguinal ring; death. This patient, a man aged thirty years, was seen in May last, in consultation with Dr. C. Z. Weber, of Norristown, who five days before had been called to treat him for abdominal pain and vomiting, of one day's standing. There was no fever, but the vomiting soon became stercoraceous, so that Dr. Weber, after securing only a few scybalous masses as the result of rectal injections, advised operative exploration. The family at first refused to give

permission to surgical interference, but finally consented.

When we saw the patient in consultation his temperature was 100.4°, pulse 120; he was slightly delirious, and was troubled with persistent hiccough. Vomiting had consisted of feces, and there was a fecal odor to the breath; but the abdomen was flaccid and not tympanitic. There was thought to be slight distention of the abdomen in the epigastric region. Pressure on the abdominal wall caused gurgling, and after etherization a sort of swashing sound was elicited in the intestines when alternating pressure was made with the hands. The patient had no special pain in abdomen or elsewhere. There was a history of a former inguinal hernia on the left side, which had always been controlled by a truss. At the present time no swelling or prominence existed in the groin.

An incision in the median line of the abdomen at once disclosed congested small intestine; and my fingers, immediately carried to the left internal inguinal ring, found the small intestine fastened there. A portion of the wall of the bowel had entered the ring as in a Littré hernia. It was easily disengaged from the hernial opening. There were no adhesions.

The man's condition was such that it was not thought wise to search for other points of obstruction, since the obstructive constriction relieved was sufficient to account for the symptoms. The delirium and hiccough continued, and death occurred on the second day.

CASE III.—Fatal strangulation of the bowel by a persistent vitelline cord. The man, a patient of Dr. H. A. Stout, of Wenonah, was beyond middle age and had suffered with complete obstruction of the bowels for five days. When I saw him his temperature was below 96°, his abdomen greatly distended, and he had stercoraceous vomiting. Preparations were made for an immediate exploration. During the hour that was consumed in preparing the room for operation and in sterilizing instruments the patient's extremities became cold, and his face covered with clammy sweat; and he died collapsed just as etherization was about to begin.

The autopsy showed no evidence of peritonitis, but great distention of the small intestine down to a point about sixteen inches above the ileocæcal valve. The bowel from this point to the cæcum was collapsed and deeply congested. Investigation showed that this loop of bowel was encircled by a thin

cord of tissue, looking very like white string of about the size used for tying grocers' parcels. This band or cord, which was thirteen centimeters long, was attached at one end to the parietal peritoneum on the front of the abdominal wall, and at the other to the mesentery above the upper portion of the constricted bowel. From another portion of bowel hung a pedunculated mass of tissue,  $4\frac{1}{2}$  centimeters long. The thread-like band previously mentioned ran through a little opening in this appendage, as a cord is run through a pulley. The appendage was attached to the intestine opposite the mesentery, but had no opening in it as would be expected if it were a Meckel's diverticulum. It may have been an altered diverticle. The constriction of the bowel by the thin, white, round cord was so tight that the portion of intestine toward the cæcum had a dark line, at the bottom of the groove made by the cord, similar to the congested gangrenous line often seen in tightly strangulated hernias.

The specimen was shown and the case reported at the meeting of the Philadelphia Pathological Society in October, 1897, since which time I have concluded that the cord was a vestigial structure—the remains of the omphalo-mesenteric or vitelline duct.

Strangulation by such embryonic structures is not very rare; though the accident occurs more frequently probably from Meckel's diverticulum than from a cord remaining as a vestige of the omphalo-mesenteric vessels alone.

Dr. Riesman read before the Pathological Society last May a paper on Meckel's diverticulum and the omphalo-mesenteric duct,\* which confirms the opinion I arrived at some time after presenting the specimen.

Relief could have most readily been given to this man by early operation. All that was required was to tear or cut the thread of tissue that constricted the ileum.

These cases show the importance of early operative interference. We must all learn that purgatives are dangerous in suspected intestinal obstruction, and that a surgeon should be called in consultation as soon as enemas sufficiently given fail to relieve the obstruction. Many lives will be saved by the recognition of the necessity of such a course of treatment.

*SANATORIA AND SPECIAL HOSPITALS  
FOR THE POOR CONSUMPTIVE AND  
PERSONS WITH SLIGHT MEANS.\**

BY JAMES M. ANDERS, M.D., PH.D., LL.D.,  
Professor of the Practice of Medicine and of Clinical Medicine in the Medico-Chirurgical College, Philadelphia;  
Attending Physician to the Medico-Chirurgical and Samaritan Hospitals, Philadelphia; etc.

Underlying the diversity of opinion concerning certain details there is a unity of thought among phthisio-theraputists as to the superiority of institutional treatment of pulmonary tuberculosis over the ordinary methods.

The accumulating scientific knowledge and practical observations of the last quarter of a century have been preparing thoughtful and progressive physicians for a movement favoring hospital and sanatorium treatment. These new methods have not been advanced suddenly and without premeditation; from an evolutionary standpoint they have not been a "short and easy thing," but have been based upon an increasing exactness of knowledge concerning the infectious nature of tuberculosis, the factors entering into susceptibility to the disease, the conditions favoring its spread and those that are antagonistic, the doubtful utility of so-called specific remedies, the value of hygienic improvements, of fresh, pure air, and the precise arrangement of every hygienic and dietetic detail. As the facts enumerated were more and more fully appreciated in the past, special hospitals and sanatoria were at length provided for tuberculous patients; it was the amalgamation, so to speak, of the long list of successive truths previously established bearing upon an ubiquitous human affliction that prepared the way for the recognition of the true principles of treatment, as expressed in well-arranged institutions. In view of this fact, it seems to me that, although little provision has been made for the institutional treatment of tuberculous cases, particularly in America, we are entering upon a new era in the management of phthisis, and one that offers most promising results; a gleam of hope and brightness has fallen upon a hitherto most unfortunate class, stricken with a serious malady.

To England belongs the credit of having been the first to provide special hospitals for the poor and needy consumptive, and whilst the object of that municipal provision has long since commended itself to the practical judgment of progressive physicians and sani-

\* Presented to and read by title before the American Climatological Association, 1898, at Bethlehem, N. H.

tary officials alike, yet little has been accomplished elsewhere in the direction of establishing charitable institutions of this sort. In an article on "Hospitals and Sanatoria for Consumptives Abroad," read before the Boston Society for Medical Improvement December 13, 1897, Dr. Edward O. Otis\* gives a graphic description of the four London hospitals for chest diseases—the Brompton Hospital, City of London Hospital, Royal Hospital, and the North London, at Mt. Vernon, Hampstead Heath. These institutions "are supported by voluntary contributions, with more or less of a fixed income from invested funds," and "all are practically free, a nominal charge of a few shillings being made in a few, with an entrance fee."†

The value of special hospitals for the care and treatment of consumptives is emphasized by L. F. Flick,‡ who says: "In England during the last forty years there has been a reduction of fifty per cent. in the mortality from tuberculosis, as a result of isolation in special hospitals." This writer continues: "In the Kingdom of Naples the disease has been nearly exterminated in one hundred years by a system of isolation and disinfection or rather destruction of infected material." To prove what can be accomplished to diminish the mortality from phthisis by special hospitals, Dr. Tatham, inspector in the office of the Registrar-General of England and Wales, has furnished to Dr. S. A. Knopf|| the following statistics for those two countries:

**MORTALITY BY PULMONARY PHTHISIS FOR 1,000,000 INHABITANTS.**

1870.....	2410
1875.....	2202
1880.....	1869
1885.....	1770
1890.....	1682
1895.....	1468

Says Archibald Kerr Chalmers:¶ "From 1860 to 1895 there has been a reduction in the deaths from tuberculous disease of 39.1 per cent. in England and Wales, in Scotland of 36 per cent." I have found from an examination of the literature and of the available official statistics that in all great cities in which active measures have been adopted to obviate the spread of tuberculosis, particularly in London, Berlin, Glasgow, and New

York, there has taken place a decided though gradual decrease in the death-rate from this fell disease.

The subjoined table shows the steady decrease in the number of deaths from pulmonary consumption in Philadelphia, of both sexes, for twenty years (though but feeble steps have been thus far taken to prevent the spread of tuberculosis), beginning with 1876, when the increase in population is taken into consideration:\*

Year.	Population.	Males.	Females.	Total.
1876.....	825,504	1288	1388	2676
1877.....	850,856	1142	1207	2349
1878.....	876,118	1154	1337	2491

¶ "The Causation of Tuberculosis and its Prevention by Legislation," *Practitioner*, June, 1898.

\* Modified from the annual report of the Bureau of Health, Philadelphia, 1896.

† Report of the Pennsylvania Society for the Prevention of Tuberculosis, 1898.

The rate of decrease in the death-rate from phthisis in Philadelphia has been more gradual than in certain other leading municipalities—*e.g.*, London and New York—and the principal reason is that special hospitals for the reception of patients suffering from this disease do not exist to a similar extent in the former city. If any additional evidence be needed to show that special hospitals for pulmonary tuberculosis lessen the mortality from this disease, it is furnished by the well-established law that the disease clings with great tenacity to private houses, unless proper sanitary measures be introduced, so that one case in a given house is apt to be followed by a second, and the greatest danger to the healthy individual is protracted exposure to the bacillus-laden atmosphere of an infected house or apartment. Arthur Ransome\* remarks pertinently: "Most of the differences in tuberculosis rates of localities are due to the greater or less healthfulness of the occupations, to the amount of air-space in the workshops, the cleanliness of the surroundings, the nature of the dust to which the work gives rise; but another, and perhaps a still more important, factor in the production of tuberculosis is the existence in certain localities of infected houses, or even of infected areas." Such observations render it clear that isolation and disinfection are imperatively demanded for the thorough accomplishment of an early extermination or greatly diminished diffusion of the disease.

Hospitals for consumptives, however, located in densely populated centers do not offer advantages in any wise comparable to those of modern sanatoria situate in a suburban locality, affording a purer atmosphere and improved environing conditions. The principal objects of this paper are to show the paramount value of sanatoria and the urgent necessity for the construction of an adequate number of these institutions for the treatment of consumption in its earlier stages in persons having small means and in the needy poor, although the best means of caring for the advanced cases (in special hospitals) will also be indicated.

The Adirondack Cottage Sanatorium, under the direction of Dr. E. L. Trudeau, is a good example, of which more are urgently needed; only patients are admitted who cannot pay more than five dollars per week, thus enabling those possessed of limited means to

obtain the superior advantages of a favorably located, well arranged, and well officered sanatorium. There is, additionally, a small free-bed fund "which varies according to the yearly contribution, and there are generally at the institution from five to six beds filled by free patients." In answer to a personal letter of inquiry, Dr. Trudeau writes: "It is true that only a small percentage of the cases requiring such treatment can be admitted to the sanitarium, and the applications are greatly in excess of our accommodations." It is a lamentable fact that for the great host of tuberculous poor there is an almost absolute lack of special sanatorium accommodation in this and most other countries. The patients belonging to this category who are not provided for constitute sources of danger to well persons, and even to susceptible individuals occupying a higher social rank, and who, although acquainted with the means of prevention, are unavoidably exposed to the infection as the result of contact in the ordinary pursuits of life. Embodied in a report of the Board of Health of the City of New York to the mayor, and included in the measures subsequently adopted by the said Board for the prevention of pulmonary tuberculosis, I find this statement: "We are convinced that no other factor is so potent to-day in perpetuating that ominous death-list from pulmonary tuberculosis as the lack of proper facilities for the *poor* (*italics mine*) of this city stricken with this malady."\*

The most trustworthy test of the combined sanatorium and climatic treatment has been made at the Adirondack Cottage Sanatorium (before referred to), and as the working class of patients only are there admitted, the results obtained at that institution may be taken as a safe and true index of its value. "Little stress is laid on the administration of drugs, except when necessary to relieve symptoms, but cod-liver oil, the hypophosphites, and arsenic are quite generally made use of." The practical results are thus fairly and conservatively given by Dr. E. L. Trudeau: † "If all attempt at classification is abandoned, and the gross results obtained in all patients admitted to the sanatorium are considered, it may be stated approximately that twenty per cent. are apparently cured, and that in thirty per cent. more the disease

\* "The Susceptibility to Tuberculosis under Different Conditions," quoted in *Philadelphia Medical Journal*, July 16, 1898.

\* Communication to the Board of Health of New York, January 11, 1897, by Hermann M. Bigg, M.D., and T. Mitchell Prudden, M.D.

† "Sanatoria for the Treatment of Incipient Tuberculosis," *New York Medical Journal*, Feb. 27, 1897.

is more or less permanently arrested. If the most favorable of all cases admitted are separated under the term 'incipient,' the proportion of cures would be as high as from thirty to thirty-five per cent., and the importance of making an early diagnosis and of the immediate application of radical measures is strongly emphasized by this experience." From the latter statement it is seen that of the earlier or "incipient" cases, in addition to the thirty to thirty-five per cent. of cures, "in thirty per cent. more the disease is more or less permanently arrested." As to the practical value of this method, Trudeau\* further says: "The best results in treating incipient tuberculosis are obtainable in special sanatoria situated in good climates."

In Dr. Brehmer's Sanatorium at Goersdorf, founded in 1859, from twenty-four to forty-four per cent. of the cases were apparently cured or had the disease arrested. Alpine sanatoria show even better results.† Otis‡ states that the results at Falkenstein "from 1876 to 1886, of the patients who have been kept under observation since their discharge, are 13.2 per cent. of complete cures and 11 per cent. of relative (arrested), a total of 24.2 per cent.; 60 per cent. or more are improved." Again, at Hohenhonnef, about 15 per cent. are considered cured and 68 per cent. improved. The average duration of residence at the two last mentioned sanatoria is only three months. It is scarce necessary at the present time to multiply examples to clearly demonstrate the power of well-organized and intelligently administered sanitariums to benefit, arrest and even absolutely cure pulmonary tuberculosis. I might have, had I deemed additional evidence important, selected still other institutions whose results are still more strikingly favorable than those already cited (e.g., Winyah Sanitarium, at Asheville, under the charge of Dr. von Ruck,§ and the Loomis Sanitarium for Consumptives||). Hermann Weber,¶ after an extensive personal experience, holds that "treatment at good sanatoria promises more than ordinary treatment at hotels and 'pensions' without strict medical supervision."

\* *Loc. cit.*

‡ *Loc. cit.*, p. 23.

§ I am aware that the basis of treatment at this institution cannot be said to be climatic and dietetic merely.

|| "Methods of Treatment at the Loomis Sanitarium for Consumptives," by Dr. J. Edward Stubbett, *Philadelphia Medical Journal*, March 2, 1898.

¶ *Philadelphia Medical Journal*, July 16, 1898.

To show the imperative necessity for the creation of these eminently satisfactory institutions, I need only point to the methods generally in vogue in the United States, France, and other countries, either of segregation in separate wards of general hospitals, or, as unfortunately happens still, of admission into the wards occupied by those ill of other diseases. In this connection it is but fair to state that the obvious element of danger to patients stricken with other forms of illness in a ward from the presence of a consumptive is probably quite generally appreciated at the present time by the medical staffs of our general hospitals, but in many instances separate wards cannot be furnished. In the absence of special accommodations the consumptive either meets with a denial of admission to those institutions (e.g., in the Presbyterian, Howard and Pennsylvania and other hospitals of Philadelphia—*vide table*) or he is allowed to occupy a bed by the side of those who are at the time susceptible to tuberculosis (e.g., patients afflicted with typhoid fever, influenza, diabetes mellitus). To show that it is not a gratuitous assumption to claim that little appropriate provision has been made for this large class of consumptives, I have collated facts and data which cannot fail to carry conviction. In the city of New York the Department of Public Charities is not able to provide separate accommodations, "excepting to the most limited extent, even for advanced cases, and as a result actual isolation does not exist in any of the municipal institutions. In every one of the institutions of the Department of Public Charities and the Department of Correction consumptives are found occupying beds in general wards of the various hospitals, associating with healthy prisoners in the cells, and in the greatly overcrowded workrooms of the workhouse and the penal institutions."\* As will be seen hereafter, however, New York City, through the continued efforts of its health department, has secured an annual appropriation for the support of a small percentage of the poor consumptives in special hospitals. That city has, comparatively speaking, the best accommodations in the form of special hospitals (*vide infra*). The table following is clearly indicative of the lack of special hospital accommodation for consumptives in New York City, though far in excess of that

\* Communication to the Board of Health of New York City, by H. M. Biggs and T. M. Prudden, 1897.

afforded by other cities. It also proves that the doors of the general and many of the "city" hospitals are closed to consumptives without means.

general wards in all stages of the disease. But it is not necessary to analyze this table any further; it speaks for itself, and in no uncertain tones, rendering clear the

Name of institution.	Cases of pulmonary tuberculosis admitted.	Admitted into general wards.	Special provision.
Roosevelt Hospital.....	Yes (all stages).	Yes.	No.
Metropolitan Hospital.....	Yes (all stages).	No.	Special wards.

St. Mark's Hospital.....	Yes (a few as emergency cases).	Yes (fair sanitary precautions).	No.
Presbyterian Hospital.....	Yes (a few as emergency cases).	Yes (fair sanitary precautions).	No.
Mount Sinai Hospital.....	Yes (a few as emergency cases).	Yes (fair sanitary precautions).	No.
German Hospital.....	Yes (a few as emergency cases).	Yes (fair sanitary precautions).	No.
Bellevue Hospital.....	Yes (a few as emergency cases).	Yes (fair sanitary precautions).	No.

In reply to a letter of personal inquiry, Dr. Vincent Y. Bowditch, of Boston, stated: "There is a lamentable lack of hospital accommodation here for the poor consumptives, the only institutions of the kind in the city being three comparatively small ones for advanced cases. Tuberculous cases are received in most of the hospitals here when not in the advanced stages, but no special provision is made for them, I regret to say, and the cases are received in the general wards."

The following is a tabulated statement of the conditions under which consumptives are received, if at all, in the principal hospitals of Philadelphia, and of the special facilities afforded for their care and treatment:

backwardness of Philadelphia with reference to proper facilities for the treatment of phthisis.

The high mortality-rate of pulmonary tuberculosis, particularly among the lower class, under existing methods of treatment is another reason that justifies an appeal to the benevolent and philanthropic for immediate action. For example, in Philadelphia the average number of deaths from all causes during the ten years ending January 1, 1897, was 22,614, while the average from consumption during the same period was 2628 cases, or 11.6 per cent. of the total death-rate.\* The percentage of all deaths due to pulmonary consumption in adult life, however, is much

Name of institution.	Cases of pulmonary tuberculosis admitted.	Admitted into general wards.	Special provision.
German Hospital.....	Yes (all stages).	No.	Special wards with special nurses.
Episcopal Hospital.....	Yes (all stages).	Yes.	No.
Howard Hospital.....	No.	No.	Any cases discovered are put into a separate room.
Methodist Hospital.....	Yes (incipient stage only).	Yes (observe rigorous disinfection).	No.
Pennsylvania Hospital.....	No.	Cases discovered are treated in general ward.	No.
Presbyterian Hospital.....	No.	.....	.....
Medico-Chirurgical Hospital	Yes (during winter season for class demonstration).	Yes (observe rigorous disinfection).	No.
Philadelphia Hospital.....	Yes (all stages).	No.	Special wards.
Jefferson College Hospital..	Yes (incipient stage only).	Yes.	No.
St. Joseph's Hospital.....	No.	.....	.....
St. Agnes' Hospital.....	Yes (all stages).	No.	Special wards.
Samaritan Hospital.....	No.	Cases discovered treated in general ward (strict disinfection observed).	No.
University Hospital.....	Yes (only during winter for class demonstration).	Yes (strict disinfection observed).	No.
Polyclinic Hospital.....	No.	Cases discovered treated in general wards.	No.

This table proves that not a single general hospital in Philadelphia is competent to treat properly consumption in its earlier stages; six of these institutions refuse to accept them in any stage, four have provided special wards, two treat only early cases in the general wards, while three admit them into the

higher than stated above, and this is especially true of the needy class and those with slight means.

The following data have been obtained

\*Annual report of the Board of Health (Philadelphia) for 1896.

from the records of the Philadelphia Hospital, which receives only the city's poor stricken with phthisis, through the kind aid of Dr. A. C. Morgan, the resident physician: During the six months ending June 30, 1898, seventy-one patients died in the special consumptive wards, and during the same period seventy-five were discharged, with fifty-two patients in the wards June 30. Again, the average percentage of the total death-rate in the Philadelphia Hospital in recent years was nineteen per cent., hence the percentage of deaths from pulmonary tuberculosis in this institution, to which are admitted only the pauper class, is nearly double that of the city of Philadelphia (11.6 per cent.). Moreover, from the *Monthly Bulletin* (December, 1897) of the State Board of Health of New York I gather that in 1896 phthisis caused 10.8 per cent. of the total mortality in that State, and it has varied in past years only from 10.6 to 11 per cent.

The consumptive poor that seek admission into the Philadelphia Hospital are found to be in all stages of the affection, though in the majority of instances, perhaps, they are in the advanced period of the disease. May not the higher percentage of deaths from phthisis in the Philadelphia Hospital, as compared with the percentage of deaths from this disease in the city as a whole, be due to the cases having progressed to a late stage at the time of admission? At first glance an affirmative answer would seem to be the correct one, but a few words of explanation only are needed to permit a fuller appreciation of the facts. As stated before, seventy-five of the phthisical patients in the Philadelphia Hospital were discharged during the six months ending June 30, 1898

(about the same number as died during this period), and a similar showing is made by the figures for 1895 and other previous years. A fair percentage of those discharged are improved, and in a preponderating proportion the discharge is granted upon the patient's own request. Moreover, it is to be recollected that the total annual death-rate for all diseases in the Philadelphia Hospital is inordinately high for the aggregate number of cases treated—a circumstance that tends to lessen the relative percentage of deaths from phthisis in this institution, as does the fact, also, that the average length of sojourn in the Philadelphia Hospital is only about three months. After due allowance is made for all modifying conditions, the data gleaned from the records of the Philadelphia Hospital show the death-rate in tuberculosis among the poor, under existing methods of treatment, to be insufferably high.

Upon examining the official reports, it is seen at a glance that the same ratio that was shown to exist between the percentage of the total number of deaths due to pulmonary tuberculosis in Philadelphia and that of the mortality of the Philadelphia Hospital due to the same cause, viz., nearly two to one in favor of the latter institution, obtains as to the question of the frequency of occurrence, the disease being almost twice as common among the lower as the upper class of society. As tending to corroborate the view that the working class and the pauper element, to be found in overcrowded districts, are peculiarly prone to the affection, let me borrow the words of L. F. Flick, a calm, true observer of phenomena concerning tuberculosis in its varied phases: "From my own experience I am under the impression that

IN EACH 1000 DEATHS FROM ALL CAUSES THERE WERE FROM

DISTRICTS.*	All zymotic diseases.	Typhoid fever.	Scarlet fever.	Diphtheria and croup.	Diarrheal diseases.	Consumption.	Acute respiratory diseases.

\*The sanitary districts into which the State is divided are as follows: Maritime District: Includes New York, Brooklyn, Long Island, Staten Island, and Westchester county. Hudson Valley District: All the counties on either side of the Hudson River, except Westchester, to and including Albany and Rensselaer. Adirondack and Northern District: The northern section of the State—the counties of Washington, Warren, Hamilton, Essex, Clinton, Franklin, St. Lawrence, Jefferson, and Lewis. Mohawk Valley District: Schenectady, Schoharie, Saratoga, Montgomery, Fulton, Herkimer and Oneida counties. Southern Tier District: The seven counties along the southern border of the State. East Central District: Sullivan, Delaware, Otsego, Madison, Chenango, Onondaga and Courtland counties. West Central District: Cayuga, Tompkins, Seneca, Schuyler, Ontario, Yates, Livingston, Genesee and Wyoming counties. Lake Ontario and Western District: Oswego, Wayne, Monroe, Orleans, Niagara and Erie counties.

seventy-five per cent. of all cases of tuberculosis occur among the poor," and, he adds, "need treatment in properly equipped sanatoria."

The statistics of the Board of Health of New York also show phthisis "to be relatively most prevalent in crowded districts, and inferentially among the lower class of people with inferior sanitary surroundings."\* The above table demonstrates the absolute correctness of this assertion.

In response to a note of inquiry, Dr. Leroy W. Hubbard informs me that "in 1897 there were reported to the Sanitary Board of New York City 9708 cases of pulmonary tuberculosis, and indications are that the number this year will be about the same." As the majority of these cases are from the various charitable institutions, this statement represents fairly the number of poor consumptives in that city.

The data collated in the table below show the number of cases of phthisis treated in the out-service of the principal hospitals of Philadelphia for a term of years; also the percentage of cases of the whole number of medical cases treated in these dispensaries. It is not claimed that the statistics compiled below represent accurately the number of poor consumptives in Philadelphia, since many of the patients probably made application at more than one institution during a year, and others (about five per cent.) came from points beyond the limits of the city. On the other

treated in special hospitals or sanatoria, and thus the disease be more rapidly excluded from the mortuary records.

Biggs and Prudden\* state that nearly 9000 cases of tuberculosis were reported to the bacteriological laboratories of the Health Department of New York City in 1896, and nearly 6000 deaths resulted from this disease. They continue: "It is conservatively estimated that at least 20,000 cases of well developed and recognized pulmonary tuberculosis now exist in this city, and an additional large number of obscure and incipient forms of the disease."

Having reviewed at considerable length the existing conditions, and having demonstrated that they fall short of the requirements and advantages necessary for the successful treatment and care of the consumptive poor, the query arises, What is the remedy? Obviously, to do nothing or to continue to maintain an indifferent attitude toward the question means, on the part of any professional organization or municipality, retrogression. Increased accommodation for the reception and treatment of consumptive patients is an imperative necessity, and in attempting to answer the query I proposed before I shall classify the cases into three large groups, and point out the provision that should be made for each respectively.

*Group I.*—To this category belong the cases that have reached an advanced stage; the disease is neither curable nor arrestable,

hand, by no means all of the working class afflicted with phthisis receive treatment at the various charities, so that the figures given below are far from being in excess of the actual number of poor phthisis patients, and yet they serve to indicate how numerous the walking patients are, who for their own interests and those of the public ought to be

as a rule; they form a distinct class, considered from the standpoint of treatment, and need only to be made comfortable until death terminates all. These patients do not require climatic sanatoria, but special hospitals are necessary in order to cut off every possible channel of communication for the infection between themselves and healthy uninfected individuals, and this I hold to be impossible if

\* F. C. Curtis in response to a written request for information addressed to the Board.

\* Loc. cit., p. 29.

admitted into general hospitals, however carefully they may be segregated. The few cases belonging to this class in which marked improvement followed confinement in a special hospital should be removed to a sanatorium, or, in other words, they should be treated in the same manner as Group II (*vide infra*).

The St. Joseph's Hospital for Consumptives, in New York City, where the patients received are for the most part in an advanced stage of the disease, is doing laudable work, and is the kind of institution to meet the demands of this group. Not less than 1500 consumptives are annually admitted here, at an average daily cost of fifty cents per capita. New York City also affords two other hospitals devoted exclusively to the treatment of consumptives, namely, the Seton Hospital, Spuyten Duyvil (150 beds); the Loomis Hospital Sanitarium (New York branch for incurables, with about fifty beds). Again, the Department of Health, New York City, has constantly in the Seton Hospital and the Colored Home and Hospital about eighty patients, whose care and maintenance are provided for by an appropriation, at the rate of one dollar per day. For the care of the consumptive poor of New York City there are approximately 1000 beds in the different hospitals. It might be mentioned in this connection that the subject of the proper treatment of consumptives is at present also claiming the attention of the health authorities of the State of New York, and, speaking with reference to the United States only, that State is in the vanguard so far as special and general measures to prevent the spread of phthisis are concerned. As I said before, in the quotation from Dr. Bowditch's communication, there are three comparatively small special hospitals for advanced cases in Boston, the largest being the Free Home for Consumptives, in Quincy Street, Dorchester, an admirable (private) institution.

The Rush Hospital for Consumptives, in Philadelphia, with an average of fifteen cases, aims to admit only the most hopeful cases, but examples of advanced pulmonary tuberculosis are often received, owing to the irresistible pressure of influence. At Chestnut Hill, near Philadelphia, there is a hospital for the consumptive poor, under the control of the Philadelphia Protestant Episcopal Mission, where patients in all stages of the affection are treated.

According to the ground here taken, a municipal hospital for the consumptive poor, while a most praiseworthy charity, should, in

order to accomplish the most good and to work the least harm, admit only patients in the last stage of the disease. There is demanded the creation of special climatic sanatoria for the treatment of the earlier stages.

The consumptive patients among the lower class, in the incipient\* stage, give us two additional groups when therapeutically considered: Group II, the pauper class, or the true wards of the city or State (these are at present compelled to seek admission to the general hospitals, without success as a rule, except in the case of the purely public charities), and Group III, those possessing small means, and composed largely of skilled mechanics and the working class.

From the facts previously adduced concerning, first, the excellent results obtained in climatic sanatoria; secondly, the relatively increased prevalence and mortality of phthisis among the lower class in overcrowded localities; and thirdly, the utter lack of special sanatoria for their accommodation, it is clear that for the latter groups there should be provided without delay appropriate institutions. It is equally clear that as a first step a strong and universal professional sentiment in support of the treatment of this disease in sanatoria is necessary; a more crying need, however, is a healthy, aggressive public sentiment, but to bring about the latter, time and the combined and well-directed energies of local and general boards of health, of health officers, and the progressive element of the medical profession are required. Happily, sanitary authorities are alive to the necessity for the adoption of suitable restrictions to diminish the prevalence of this dread disease; and they can do much by formulating ordinances, the distribution of circulars of information, etc. Says Dr. Benjamin Lee:† "Those whose official positions make it their duty to do all in their power to extinguish disease, diminish the death-rate, and prolong longevity, entertain convictions so positive as to lead them to believe in the possibility of the adoption of measures which shall restrict the spread of the disease, and thus add an incalculable number of years to the aggregate of human life." The health authorities of the city of New York have taken advanced ground, and

\*I here employ the term "incipient" for the most favorable cases, rather than the first pathologic stage.

† "The Present Attitude of Sanitarians and Boards of Health in Regard to Pulmonary Tuberculosis," *Journal of the American Medical Association*, Oct. 30, 1897.

very properly placed pulmonary tuberculosis among notifiable diseases.

I heartily approve of the recommendation frequently made by sanitarians, that practical information and suggestions concerning the best means to be adopted to limit the ravages of this fell affection should be systematically and earnestly diffused, until the required knowledge, particularly with reference to the value of such measures as isolation, hygiene, and climate, shall have been thoroughly popularized; yet I am wholly convinced that to ripen sentiment, and to gain the approval of the masses in the movement to secure this ideal plan of treatment, it will be necessary to pursue an educational policy for years to come. Conversely, it is to be recollected that, as pointed out by Trudeau,\* "the education the patients receive at the sanitarium as to the nature of their disease and the methods to be relied upon in combating it is of the utmost value to them in enabling them to care for their health and avoid relapses after they have left the institution." Doubtless the erection and maintenance of an adequate number of sanatoria would prove to be the means, also, of educating the communities in which they might be located.

While it were most desirable that Group II, composed of the pauper element of society afflicted with incipient tuberculosis, should receive the benefits of sanatoria situated in the best climates, it is scarcely feasible. Fortunately, the results obtained at sanatoria situated near large cities, in localities devoid of special climatic advantages, but having a comparatively pure, fresh atmosphere, are also surprisingly good. Witness the Sharon Sanatorium, which is situate a few miles from Boston, under the charge of Dr. Vincent Y. Bowditch; it reports twenty-five per cent. of arrested cases, and a much greater percentage of improvements.

Hence, whilst the basis of the typical plan of treatment is hygienic, dietetic, and climatic, we can, by paying attention to the selection of a favorable location in an easily accessible rural district, preferably one well sheltered in the woodland, secure a uniform temperature and a purified atmosphere. I have elsewhere shown that forests tend to maintain an equality of climate, both as to temperature and relative humidity, so that forest resorts possess certain unmistakable advantages for the consumptive sufferer, particularly pine groves,

on account of their terebinthinate exhalations.\*

At sanatoria the hygienic details, including an appropriate dietary, are rigorously carried out under the constant surveillance of a competent medical officer, and right here lies the principal reason why excellent results are so uniformly obtained; and whilst these institutions should be invariably under State and municipal authority, I feel convinced that the group of cases under consideration (the pauper element of society in the earlier stages) should not be treated in cities, but in sanatoria near them, and always in the best available climate. This class of patients should perform certain duties under the direction of the physician in charge that would diminish the current expenses of the institution. The cities pursuing this plan for incipient or favorable cases could furnish accommodation in the form of sanatoria for little if any additional outlay, since the expenses per capita would be but little in excess of that required to keep them in general, city or almshouse hospitals with their antihygienic surroundings. Unquestionably, any method of treatment that would greatly increase the percentage of "cured" or "arrested" cases among the poor would tend to lessen municipal poverty, on the one hand, and, as a natural corollary, would save the community needless expenditures for the support of families left without a head on the other.

For Group III, or persons having slight or comparatively small means, who could afford the expense of from five to ten dollars per week, sanatoria in a good climate are urgently needed.

I have previously quoted the results obtained at Sharon, Massachusetts, from the sanatorium treatment of phthisis near large cities. Dr. Vincent Y. Bowditch,† who is the medical director of the Sanitarium for Pulmonary Diseases, wisely remarks that he "should not be so foolish as to claim results equal to those coming from a radical change of climate, such as is possible for the wealthier classes;" he contends, however, that what has been accomplished at Sharon is vastly more satisfactory than any attempt to treat patients at their homes, or in the office, in this part of the country.

This sanitarium has been established for

\* "House Plants as Sanitary Agents; Sanitary Influence of Forest Growth," by the author, p. 312.

† "The Treatment of Phthisis Near our Homes." Read at the annual meeting of the Massachusetts Medical Society, June 10, 1896.

\* *Loc. cit.*, p. 14.

the treatment of incipient pulmonary diseases only in patients who are in reduced circumstances, advanced cases not being admitted. Institutions of this character are entirely suitable for patients belonging to Group II, or those who cannot afford to pay any price for board; for Group III, however, or persons possessing small means, it were desirable, and it is entirely feasible, to supply similar institutions in localities presenting claims to climatic advantages. Dr. Bowditch has shown that "the sanatorium treatment of consumption, even in harsh climates, takes a very high rank among the methods of combating the disease," and this opinion I strongly indorse as being the best mode of treating phthisis in the dependent class. I am also in full accord with those who look upon phthisis as an infectious and contagious disease, demanding the enforcement of isolation and disinfection to limit its spread.

Granting these dicta, it is my earnest hope that the therapeutic importance of pure air, an equable and cold climate, abundance of sunshine and moderate elevation, in combination, to the phthisical invalid will not be underrated, in view of the importance now justly given to the effects of a rigorous hygienic regimen under the close supervision of a competent medical officer. It seems to me we should hold fast to the well founded and reasonable opinion, that whenever practicable the combined climatic and hygienic treatment is to be advised and adopted.

It is for these reasons that I would warmly advocate the establishment of true *climatic* sanatoria. The expenditure in such institutions would not exceed one dollar per diem for each patient (about the same amount as would keep him in a general hospital), and this would be nearly, if not entirely, covered by the payment of a weekly board ranging from five to eight or ten dollars.

At the present day the danger of contagion from the consumptive (not always immediate, but sometimes remote in point of time) in general hospitals is universally admitted by all progressive physicians. The fact that cases of infection among attendants in special hospitals for consumptives rarely occur is no argument against the necessity for the separation of consumptives from well persons, but rather an argument in favor of isolation under close medical supervision. The time has come when the apathy and indifference on the part of the medical profession now existing (with few exceptions) should speed-

ily give way to an aggressive movement looking to the proper treatment of consumptives belonging to this group.

Every physician of large clinical experience must have felt keenly in recent times his utter helplessness and inability to furnish proper advice in these instances in the absence of institutions for their reception and treatment. Boards of management of our general hospitals should be entreated to establish for this large class in the immediate future sanatoria in appropriate localities, as special departments, furnished with competent medical officers. Such an undertaking, in the name of sweet charity, would be warmly welcomed by the medical profession, but more than this, it would exert a most beneficent influence *sui generis* in combating the ravages of pulmonary tuberculosis. And whilst it were much to be desired that these institutions might be purely philanthropic in their aims, as in the case of the Adirondack Cottage Sanatorium, if a graded scale of prices, as suggested above, were adopted, the deficiency, if any, in the expenses for professional care and maintenance would be small indeed, and easily met by voluntary contributions.

It would seem that philanthropists owe a duty to this particular class of invalids that has not as yet been discharged. Perhaps they have not appreciated the obligation they owe, because they have not realized the grounds on which it rests. In the case of the Adirondack Cottage Sanatorium liberal responses have followed the appeals of its president and interested friends, and it is probable that like personal sacrifice and efforts on the part of influential members of the profession would accomplish the same good practical results in other States.

That the creation of sanatoria in a given locality tends, in a remarkable degree, to diminish the number of cases of pulmonary phthisis is strikingly illustrated by the official statistics of the village of Goerbersdorf for a hundred years:

#### DEATHS FROM PHTHISIS PULMONALIS.\*

1790-1799.....	14
1800-1809.....	5
1810-1819.....	9
1820-1829.....	9
1830-1839.....	8
1840-1849.....	6
1850-1859.....	7
1860-1869.....	4
1870-1879.....	5
1880-1889.....	5

\* Quoted by S. A. Knopf, M.D., *loc. cit.*, p. 463.

Such sanatoria would, in the second place, reduce the enormous death-rate from tuberculosis, in existing and future cases, among the poorer classes, since in properly equipped sanatoria these unfortunate subjects would receive the benefits of the most approved methods of treatment in incipient or favorable stages of the affection. What I have previously stated concerning the practical results in the treatment of phthisis in sanatoria has, I trust, left no doubt in the minds of my readers as to the absolute reliability of this statement.

It is not my purpose to deal here with the subject of the treatment of phthisis among the wealthier classes, who can enjoy the advantages of open-air climatic treatment in the best localities, or the benefits of more elaborate and well equipped sanatoria, to be found especially in different European countries.\* But I wish merely to emphasize the earnest hope that private enterprise will speedily create more of these institutions for the well-to-do consumptives also, and thus diminish the danger from the diffusion of tuberculous virus, which must at present result from their occupying boarding-houses and hotels where large numbers of well persons congregate.†

In concluding this paper I hold it to be preeminently the duty of the medical profession to seek to promulgate right notions on the treatment and care of phthisical patients among State and municipal legislative bodies, the medical profession at large, and the general public. The most important work, however, now and in the immediate future is not so much to thus propagate the combined method of treatment here advocated, but to induce the members of the medical profession to translate into active measures the essence of their belief.

An organized effort to bring relief to the large class of sufferers under consideration might with peculiar appropriateness be undertaken by such an organization as the American Climatological Association. Its members should individually bear a part of the work; but before they seek to induce State and municipal authorities and philanthropists to participate in the creation of appropriate institutions for the treatment of those ill with phthisis, it is an important matter to

consider what are the proper lines on which to work, and to keep in mind modern therapeutic and hygienic demands. It has been my province to point out the course to be pursued in meeting the varied needs of the lower and working classes afflicted with pulmonary tuberculosis; I have endeavored, also, to emphasize the importance of an explicit recognition of the requirements of the three groups or subdivisions of the cases, based upon such considerations as social station, stage of the affection, and the physical condition of the individual.

Provisionally, the more salient points and inferences brought forward in this paper might be summated in tabular form under two main heads:

(a) Those that show the extent and urgency of the needs presented by the large class of phthisical patients previously considered, and the value of special hospitals and sanatoria for their treatment:

1. The statistics adduced here afford clear and convincing proof that pulmonary tuberculosis is proportionately far more common, as well as more inauspicious, among the lower than among the higher classes.

2. The almost absolute lack of proper facilities for the treatment of the poor afflicted with pulmonary tuberculosis, as shown by the tables given above, is a most potent factor in maintaining the enormous death-rate from this disease.

3. Special hospitals in which every hygienic detail can be arranged with precision are far superior to separate wards in general hospitals for the treatment of cases of pulmonary phthisis.

4. The admission to, and care of such patients in, the wards of general hospitals with those suffering from other forms of illness, as is the custom still in some, and to a limited extent in many, institutions, is to be energetically deprecated. There is serious danger of transmitting the disease under these circumstances, particularly when the breaking down or suppurative stage is reached.

5. The mortality figures show a reduction of nearly fifty per cent. in consequence of the creation and continued operation of special hospitals for consumptives (e.g., city of London).

6. Sanatoria near large cities afford better advantages than so-called special hospitals in densely populated centers, whilst climatic sanatoria, if properly situated, properly officered, and well equipped, show results that surpass those of all other known methods of

\*A good example of such an institution in this country is the Winyah Sanitarium, near Asheville, North Carolina, under the care of Dr. von Ruck.

†Fortunately, certain hotel-keepers already refuse to receive persons afflicted with pulmonary tuberculosis.

treatment, in the earlier or incipient stages of the disease.

7. Sanatoria lessen the mortality-rate of phthisis in communities in which they are situated.

(b) Points bearing upon the discrimination of cases, among the lower class, into three groups, and the remedy—an institution with distinctive characteristics—for each:

*Group I.*—The numerous cases that have progressed to an advanced and practically hopeless stage. These require every comfort and kind care, such as can be furnished by special hospitals for consumption in a healthful urban locality.

*Group II.*—Incipient cases among the poorer element. For such, sanatoria conveniently located in close proximity to large municipalities, though with special reference to such factors as purity of atmosphere and protection from chilly blasts, by natural elevations or the woodland, should be provided. It is not possible to secure for them the most salutary climates.

*Group III.*—Phthisis pulmonalis among the middle and working class, or persons having small means. The members of this group will find themselves compelled to depend principally upon private philanthropy, and probably to some extent also upon semi-State institutions; they need sanatorium treatment in the best climates, and there is no valid reason why the combined sanatorium and climatic treatment should not be attempted, since such an undertaking could be made to be almost self-sustaining.

1605 WALNUT STREET.

#### *APOCYNUM CANNABINUM.*

BY WILLIAM D. TURNER, M.D.,  
Pasadena, California.

The comments of one of your contributors on the action of apocynum cannabinum in your August number I feel are not borne out by facts, hence I make this reply.

First, *Apocynum cannabinum* and *Apocynum androsæmifolium* are so similar in their general external appearances, and grow in common in the same localities, that the inexperienced or unprincipled gatherer might easily mistake the one for the other. Even the ordinary manufacturer might easily make the same mistake.

Second, the therapeutic effects of *Apocynum androsæmifolium* are to some extent similar to those of *Apocynum cannabinum*,

though much more limited, excepting as an emetic and depressant; and from Dr. Jennings' description of the symptoms manifested in the cases to which he gave the supposed apocynum cannabinum I am justified in believing he did not administer a drug made from the true *Apocynum cannabinum*. Granting he gave the genuine article, made from the fresh herb gathered at the proper time and cured in the most approved manner, with disappointing results, that should not be sufficient evidence to condemn its use in all cases and conditions where indicated.

Thirty years' experience in the use of a medicine certainly should entitle one to greater consideration than one who had used the medicine in only three cases. This experience I have had, first using apocynum cannabinum in the year 1868, and I can truthfully say I know of no drug made from any indigenous herb growing in North America more certain in its action than *Apocynum cannabinum*. It is not in local dropsies where its curative effect is most noticeable, but in general anasarca, or cellular dropsy. It will relieve many times in cardiac dropsy with general anasarca, when not superinduced by degenerative nephritis. If the latter condition is present it is more likely to fail, or at most but temporarily relieve.

I can call to mind many cases of anasarca, ascites, hydrothorax, including cardiac dropsy, where its curative effect was marvelous. I remember a boy of eleven years who had anasarca so badly and for so long a time that on looking at his external genitals no one could tell to which sex he belonged. He had been treated for some time by two other physicians without success. Upon general examination I felt that apocynum cannabinum was the medicine called for, so I gave it continuously just short of its emetic effect. The rapid recovery and subsidence of the dropsy was almost beyond belief even to my own eyes. But he fully recovered and was well years afterward.

I gave the same to two young men, both so far advanced in cardiac dropsy as to be unable to lie down. They had been treated for months by other physicians. I gave each the same—apocynum cannabinum. To the surprise of all their friends their troubles subsided, and in three or four weeks they were able to resume their business; one of them passed a successful life insurance examination against my advice. Both of these cases

had organic changes in renal organs, and in a few months the same condition returned, and death followed.

Mrs. M., six months advanced in pregnancy, became generally dropsical, cardiac dropsy supervening. She was treated by other physicians until her condition became so alarming that a change was decided upon, and I was called. I could find no organic change in any of the organs of the body, but the conditions were so distressing that she could not lie down or sleep but for a few minutes at a time. I gave apocynum cannabinum in as full doses as she could tolerate. The dropsy speedily subsided, and she was delivered of a healthy boy at full term, and was well years afterward.

I could cite many more cases where results were equally as favorable, and a few where they were not. Indeed, I have never found an absolute specific for apparently the same condition in every case.

Professor John King refers to its use as early as 1832, as may be seen in his American Dispensatory.

Where one prescribes for a condition rather than a name, he will never find a medicine more certain in its effect than that made from the true *Apocynum cannabinum*, properly selected and prepared, either as a fluid extract, "specific" or "normal liquid."

#### CONSERVATIVE OPERATIONS ON THE UTERUS AND APPENDAGES; ILLUSTRATIVE CASES.

BY J. COPLIN STINSON, M.D., C.M.,  
San Francisco.

In deciding on an operation for the removal of an ovarian cyst or uterine fibroid, etc., we should proceed upon those lines by which the cyst or tumor can be extirpated without sacrificing the ovary or uterus. Until recently oophorectomy and hysterectomy were performed. I believe that where it is possible we should avoid removing the uterus or any portion of ovarian tissue which appears normal, even though the portion of ovary remaining be small. Resection and plastic operations should be practised when pregnancy is liable to occur and delivery at term can be conducted with safety. We should endeavor to cure our patients without depriving them of their menstrual function, as sometimes the symptoms that follow hysterectomy or double oophorectomy are more taxing than those which were present before the operation was performed.

In looking over my list of cases in which I operated or assisted in an operation for an ovarian cyst, or cystic ovary, while house surgeon at the Post-Graduate Hospital, New York, during 1893 and 1894, and since I left that institution, I find they number eighty-two; of these twenty-one were ovarian cysts; five were dermoid cysts (one double); fifty-two were cystic ovaries. Salpingo-oophorectomy was performed for the ovarian and dermoid cysts, and for thirty-two of the cystic ovary cases, while in the other twenty-four excision and plastic methods were employed.

In this relation I take pleasure in making some excerpts from a paper\* recently published by Dr. A. Palmer Dudley, of New York, on "Conservative Surgery upon the Uterine Appendages." He reported sixty-five cases in which conservative methods were employed. Of these pregnancy followed in ten—six children were born at full term; three miscarried, the first by injecting the uterus with hot water, the second by injuries received from a kick, and in the third case the history was doubtful; the tenth pregnancy is still going on. Dudley further states that he was not able to trace all the cases, but has no doubt that if all were traced he would be able to record a much larger number of pregnancies. I also quote from another authority, Mathaei,† who reports six cases of ovariectomy with resection of the opposite ovary, five of the patients subsequently conceiving and bearing living children.

The following are selected from my series of cases and reported, as they are not only unique but also illustrate well conservative work on the ovaries and uterus:

CASE I.—Diagnosis: Endometritis, moderate prolapsus uteri, retroflexion with adhesions, lateral displacement of fundus uteri, bilateral ovarian cysts. M. M., aged thirty-one, widow, has always complained of dysmenorrhea. In 1894 she had a miscarriage, from which she made a slow recovery. In 1895 she fell from a bicycle, striking the right side of abdomen against a car track. Since then she complained of pain in the abdomen and pelvis, worse on the right side; she also began to have more pain with menstruation, backaches, more pain in the pelvis, worse on walking, and some vaginal discharge. In 1895 she received local treatment for a while,

\* A. Palmer Dudley: *American Gynecological and Obstetrical Journal*, February, 1897.

† Mathaei: *Zeit. f. Gebartsh. u. Gynäk.*, Bd. xxxi, H. 2.

and later the cervix was dilated to relieve the painful menstruation. This helped her somewhat, but she was soon as afflicted as ever. I saw her June 7, 1897. She was rather pale, looked careworn, but her general condition was fairly good. She complained of backache, pains across the lower abdomen and in the pelvis, more severe on the right side, had some vaginal discharge, and menstruation was always painful. Examination showed tenderness over the lower part of the abdomen, more on the right side of the pelvis, cervix low in the vagina, fundus uteri somewhat enlarged, retroflexed, drawn over to the right side of the pelvis, and fixed by adhesions; ovaries enlarged and tender to the touch, tubes apparently normal. Examination under chloroform two days before operation confirmed the above.

On June 13, 1897, assisted by Dr. George Gross, of San Francisco, I made operation; chloroform being administered by the drop method. The dysmenorrhea, endometritis, retroversion with adhesions, and the prolapse of the uterus received appropriate treatment. An incision two inches long was made slightly to the left of the linea alba; immediately above the pubes, dividing the skin fat and fascia, blunt division of the left rectus was made and the peritoneum opened. She was now placed in the Trendelenburg position and pelvis examined. On account of the depth of the fundus uteri and the adhesions fixing the organs, I found it necessary to enlarge the incision slightly, the entire length being now  $2\frac{3}{4}$  inches. The fundus was found drawn over considerably to the right side of the pelvis. The adhesions were separated with the fingers after some difficulty, and the fundus was drawn into view with double tenaculum forceps. The right ovary and tube were examined; the tube was normal; the ovary contained a cyst the size of a large walnut. This was evacuated, about five drachms of serous fluid escaping. It was then excised and the cut edges of the ovary united with continuous sutures of fine chromicized catgut. The ovary was now about one-third the normal size. The left ovary and tube were next examined. The tube was normal; the ovary contained a cyst slightly larger than that on the right side. The cyst was evacuated, removing about six drachms of serous fluid, then excised, and the cut edges of the ovary united with catgut sutures.

These are the largest cysts I have operated upon or have seen, in which the cysts were excised and plastic work done on the ovaries.

The pelvic cavity and the cul-de-sac were sponged out and the abdomen closed, without drainage, in separate layers with continuous sutures. Fine chromicized catgut was used for the peritoneum, chromicized tendon for the muscle and fascia, and very fine silk for the skin. Convalescence was uninterrupted, except for an attack of catarrhal icterus, which showed itself shortly after the operation. The jaundice had nearly disappeared two weeks after the operation. The wound healed by primary union. The silk stitches were removed on the sixth day and aristol collodion applied. She was allowed to get up on the thirteenth day, and went home on the fourteenth. All the dressings were removed in the third week, when she was permitted to go around without any bandage or support. She has menstruated regularly since the operation and there is no pain or discomfort; general condition is good; has gained eighteen pounds in weight; and has no pain or other symptoms referable to the abdomen or pelvis.

CASE II.—Diagnosis: An intraligamentous fibroid of the uterus, with adhesions to the ovary; multiple cysts of the other ovary. M. W., aged thirty-five years; married. In 1894 she began to have a copious vaginal discharge. However, since early childhood she has had a discharge (vulvo-vaginitis). In the fall of 1894 she received some form of electrical treatment for her pelvic trouble. This was not attended with distress during the treatment, but afterwards the pain in the uterus was excruciating. Since then she has had pains in the pelvis and the left side of the abdomen. In December, 1897, while lifting a bucket of water she felt a peculiar pelvic pain, which was dull in character and continued for several days. There was also constant pain in the left side. Examination at this time showed that there was milk in the breasts, and the uterus was somewhat enlarged. She continued to menstruate; the flow which she had suffered from for some time was peculiar. She would pass a drop or so of blood for three days, and on the fourth the flow would commence. The bleeding was always quite severe and lasted usually five days, and later on she would pass clots of blood. She was examined March 13, 1898, by Dr. George Gross, but the abdominal muscles were so contracted that nothing could be made out with any degree of satisfaction. On March 17 she was examined under chloroform by Dr. Gross and myself. We found endometritis; uterus somewhat enlarged, in good po-

sition and movable; left ovary enlarged about three times the normal size, prolapsed and adherent. On the right there was a mass the size of a hen's egg. It extended from the right uterine cornu, right side and posterior surface of the uterus outward into the pelvis.

On April 16, 1898, assisted by Dr. G. Gross and Dr. Burgess, I operated. Chloroform was administered by Dr. Putman by the drop method. Cervix was dilated, uterus curetted and irrigated. The vagina was then packed tightly with plain gauze. This was done to push the uterus as high as possible. A vertical incision, about two and a half inches long, was made just above the pubic bone, dividing, slightly to one side of the median line, the skin, a thick layer of adipose tissue, and the fascia; blunt division of the right rectus was accomplished, and finally the peritoneum was opened at the upper angle of incision and then torn down with the fingers to the lower angle. She was now placed in the Trendelenburg position and pelvis examined. The manipulations and the intra-abdominal work were made very easy by the pushing up of the uterus, etc., with the vaginal packing. This I think is of value. The fundus was readily located and brought to the surface. In the right cornu of the uterus was a fibroid tumor about the size of a hen's egg; it was firmly attached to the right cornu and the adjacent portion of the posterior of the uterus. The Fallopian tube was displaced downward about half an inch, being located in front of the mass, which spread out into the folds of that portion of the broad ligament which contained the vascular supply to the right ovary. The external surface of the fibroid was rather firmly attached to the inner surface of the ovary, which was about  $1\frac{3}{4}$  inches long. Its attachment to the mass was about  $1\frac{1}{4}$  inches long. The connections between the ovary and fibroid were separated, using blunt dissection, aided at times by cuts with a scalpel. This necessitated division of the broad ligament of the ovary, about  $1\frac{1}{4}$  inches. The dissection was carried so close to the ovary that no vessel was cut that required clamping. The cut edges of ovary were at once sutured with fine chromicized catgut. The freeing of the ovary cut off about three-fourths of its blood-supply. Rather than sacrifice any ovarian tissue, I trusted to the remaining blood-supply to furnish nourishment for the whole organ. A circular incision was then made around the fibroid at its attachment and origin from the uterus,

first estimating the amount of uterine peritoneum that should be left, so that the cut edges could be brought accurately together with sutures. The fibroid was freed from the muscle wall by blunt dissection, aided at times by cuts with a scalpel, and the cut edges of muscular and peritoneal layers were sutured with continuous fine chromicized catgut sutures. The left ovary was bound down by a few adhesions, which were separated, when the ovary and tube were brought to the surface. The tube was patent. The ovary was about three times the normal size and contained several cysts; two, each the size of a large hickory-nut, and another about one-third the size, were evacuated and then excised. The raw edges where ovary had been adherent were also excised and the cut edges of ovary united with continuous fine catgut sutures. This reduced the ovary to about one-third the normal size. The pelvis was sponged out and the abdomen closed without drainage as in Case I. Wound healed by primary union. Silk stitches were removed on the eighth day.

Patient was up and around three weeks after the operation, when dressings were all removed, and no bandage or support used. She menstruated May 18 to 20, 1898; no pain; quantity and quality of the flow appeared normal. She is quite well; examination shows the uterus and appendages in good position; she has no pain or other symptoms referable to abdomen or pelvis, and menstruation is normal.

These favorable results show that conservative operations, or what I think would be better called scientific pelvo-abdominal surgery,\* should be more frequently employed, as we can thus cure without interfering with the physiological actions, relations and uses of the pelvic organs.

326 KEARNY STREET.

#### THE PREVALENCE AND THE PREVENTION OF PUERPERAL INFECTION IN PRIVATE PRACTISE.†

BY GEO. ERETY SHOEMAKER, M.D.,  
Gynecologist to the Methodist Hospital, Philadelphia.

It is more than forty years since the long fought battle was won which settled once and forever the question as to whether

\*J. Coplin Stinson: *Occidental Medical Times*, "Conservative Operations on the Uterine Appendages, with Illustrative Cases."

†Read before the Philadelphia County Medical Society, Sept. 28, 18 8.

childbed fever was contagious, or was capable of being caused by an unclean touch. Bitterly was the idea resented at that time, as now, by physicians that they themselves and their clothing could be and were the carriers of death and suffering. Personal and acrimonious contests grew out of the discussion, but gradually the truth conquered and will never again be overthrown. Nearly a generation was required, however, before those having the management of lying-in establishments grasped the situation and provided for the care of women under their charge without contaminating them. Then came the development of the science of bacteriology, which without adding to or subtracting much from what was known empirically about means of infection, has enabled us to study the processes.

At present no scientific man dares question the life-saving value of cleanliness in obstetric institutions. The mortality there has steadily declined, epidemics have been banished, and instead of being one of the most dangerous, a well managed institution has become the safest place on earth for the woman in childbed. This, too, can be attained by very simple means—the action of air and sunshine in and on the buildings and fixtures; the action in addition of soap and boiling and heating on bedding, clothing, and utensils; lastly, by having clean people in charge.

Now while this is admitted by every sanitarian and intelligent layman, as well as by every physician, a curious anomaly exists in the status of what is known as the private patient, or the woman delivered at her home. Such patients die; they die in large numbers. Many more barely escape with life, and still more have minor degrees of infection which leave them more or less permanently disabled.

Because of the absence of records which summarize these results, the facts seem to attract little attention. It has been estimated by good authority that in New York and other large cities the mortality in private practise is from two to three times that of a good lying-in institution. More than one in every hundred die, and this in spite of the better condition of these patients and their better previous care. There are no records which give fairly the figures as to deaths, and none record the non-fatal infections. From the birth reports of cities would have to be omitted all cases delivered by ignorant midwives, all self-delivered, all in squalid circumstances,

as not included in the private practise under discussion. To the very few actual death reports from puerperal fever would have to be added hundreds which appear under other names, such as pneumonia, typhoid fever, malarial fever, inflammation of the bowels or peritonitis. The disclosure and proper classification of such deaths in public reports will never be accomplished for obvious reasons. In order, then, to arrive at any conception of the prevalence of puerperal infection, let any physician consider how many cases have occurred in his own circle of acquaintance, if not in his own practise. Then let him realize that he can know personally of very few labor cases.

A man who knows much of the prevalence of infection is the consulting obstetrician,\* who for well known reasons does not parade the infected cases he sees. The gynecologist too sees many, either to consider the question of operation in the acute stage, or later for an attempt to restore lost health. The statement, "I have never been well since the birth of such and such a child," is one which very often appears in the history of his patients. In fact, as he takes the history of large numbers of women, it will develop that after some one of the labors the patient was sick longer than normal, had abdominal swelling, tenderness and fever, followed by a slow recovery with general prostration and pelvic distress. Some will innocently state that they had typhoid fever or malaria immediately after childbirth. It is not uncommon to hear a physician say, in a moment of non-statistical enthusiasm, that he has never lost a case, or never has any trouble from infection in his practise; but he might profitably consider whether or not in his routine work he uses the thermometer, whether post-mortem examinations are skilfully made in his cases of death. If his memory is good as to cases and his remark will bear his thoughtful revision, then it is true because he is clean in his work.

As to the prevalence of various grades of puerperal infection in ordinary private practise, there can be no question among those in a position to know. That the woman in good circumstances must assume risks which are

---

\* NOTE.—In discussing this paper one physician stated that he had seen in consultation six puerperal septic women within the month just passed, and after the reading of the paper a physician present said to the writer that his own wife had been extremely ill with puerperal sepsis, and that the physician in charge of her was said to have under his care three other septic cases at the time.

avoidable, and which her poorer and less cultured sister may entirely escape, cannot be denied.

Some of the reasons for these anomalous conditions may be briefly considered as relating (a) to the patient; (b) to the community; (c) to the physician.

(a) The more carefully nurtured and highly developed the woman and the cleaner her life, the less accustomed is her system to resisting dirt and the less immune is she to ordinary body or habitation infections. In no other way can the fact be accounted for that more women in squalid surroundings do not die; while with far fewer chances of infection the woman in refined surroundings has trouble.

(b) The attitude of the community. The ordinary house is not arranged for modern surgery or for obstetrics. The community at present realizes the situation in regard to surgery. It is perfectly willing that careful aseptic preparations may be made in a room prior to operation. It is indeed rapidly coming to the true opinion that the place for surgery is in a building built for surgery. In regard to obstetrics the community is not, however, in the same attitude of mind. Although in both cases exactly the same sources of infection are to be guarded against—namely, contact with sheets, hands, clothing, utensils, napkins or dressings which have not been specially cleaned, or which have been exposed to direct streptococcus or staphylococcus infection—the community is not yet ready to tolerate any great disturbance of ordinary household living and sleeping arrangements. The woman with unbounded resources must use the same elaborate bed and bedding which conventional family life demands, and which she herself has used for years.

The community has become willing within the last five years to build and equip expensive hospital operating rooms whose essential advantage consists almost wholly, not in their elaborateness, but in smooth floors and walls, every corner round, and easily kept clean by soap and water. That same community would at present rebel against assigning a lying-in woman to some room in her house with recently scrubbed, carpetless floor, and the plain white aseptic furniture so familiar elsewhere. That physician would at present run risks with his popularity who should go too far in this direction, yet there can be little doubt that time will bring about many changes in the direction of simplicity in the lying-in room,

with great advantages to the patient. It is not contended that aseptic labors may not in the majority of instances be conducted in a room which has in it plumbing, heavy carpets filled with dust, several layers of wall-paper one upon the other, curtains and heavy furniture seldom moved for sweeping; or where the bedclothing may not be new and certainly has never been washed, though in constant use. It may be true that it is the custom of the community to so conduct labors, and that women regard that sufficiently good which was good enough for their mothers; yet in any consideration of the actual causes of the prevalence of sepsis, such matters must be acknowledged to have an influence, particularly on the outcome of cases otherwise critical or demanding operative interference. A demand for a specially constructed lying-in room would be Utopian, but a plea for greater simplicity and cleanliness in its furniture is not.

(c) The attitude of the physician. A far more potent and active cause of puerperal infection lies in the imperfect cleansing, or *imperfect guarding when cleansed*, of the hands of the physician, which come directly in contact with the patient, and in a certain lack of care as to the clothing worn in the lying-in room. It is very common to hear remarks from physicians and laymen about the wonderful changes which have been made in the dangers of surgery and childbed by modern discoveries. True, a new era has dawned; but unfortunately the change has been made in the possibilities of prevention, and not always in the realities as carried out by those who smile sarcastically about the necessity of attention to details. It is not to be supposed that contagions are different from what they were formerly. The same risks are assumed now as fifty years ago, when a physician visits a case of erysipelas or diphtheria and goes afterward to the lying-in chamber, while the risks are not eliminated when he rinses his hands rapidly for a minute or two in a carbolic acid or corrosive sublimate lotion.

In 1843, when the greatest teachers of obstetrics were sending forth their denunciations, their sarcasm and their humorous reflections upon those who believed in the contagiousness of puerperal fever, Dr. Oliver Wendell Holmes published his classical essay upon that subject, which did so much to convince the profession of its own responsibility. Could that essay be widely read to-day much good would follow. He

showed by instance piled upon instance, giving names and places, where a physician would attend a post-mortem examination, for example, and in the same clothing attend confinement cases, which would sicken and many would die. Take, for example, the experience of a physician in 1830, who narrates as follows: "The first was in February, . . . confined on the 4th and died on the 12th." He then attended eight women, only one of whom sickened. "Mrs. E. was confined February 28, sickened and died March 8. The next day, the 9th, I inspected the body, and the night after attended a lady, Mrs. B., who sickened and died the 16th. The 10th I attended another, Mrs. G., who sickened but recovered. March 16 I went from Mrs. G.'s room to attend Mrs. H., who sickened and died 21st. The 17th I inspected Mrs. B. On the 19th I went directly from Mrs. H.'s room to attend another lady, Mrs. G., who also sickened and died. . . . Up to the 20th I wore the same clothes. I now refused to attend any labor, and did not until April 21, when having thoroughly cleansed myself I resumed my practise and had no more puerperal fever." (O. W. Holmes, *Medical Essays*, p. 150.)

It would well repay any physician practising obstetrics to-day to read that essay. For similar examples of death and disease it is by no means necessary to go back so many years, but the excitement at that time brought out a mass of evidence, some of it in our own College of Physicians. Time has now robbed it of its personal character. The writer meets many men who, fully realizing the situation, are clean in the work. Perhaps the majority are particular. It cannot be denied, however, that a very large group of physicians exists who for various reasons make no attempt at reasonable obstetric antisepsis, and who consequently not only adopt a low standard themselves, but tend to reduce to a similar low standard the women whom they employ as nurses and the community within the sphere of their influence. Some reasons for this attitude are: supposed lack of time; lack of knowledge of a simple technique; carelessness. Some claim as an excuse that the whole matter is theoretical and more or less theatrical and temporary. They have not read the evidence. As regards the general standard in the profession there can be no doubt that it is rising, and that it has risen tremendously in this regard. Men are resigning practise now who were educated before the régime of surgical cleanliness.

Perhaps what is needed most of all at present is a widely disseminated appreciation of how simple the essential methods are. Unquestionably the busy man would have to give up antisepsis in despair if it were only to be obtained by complicated and expensive sterilizers and an elaborate series of solutions in connection with marble and glass operating rooms. From the standpoint of everyday practise, however, the matter is really not complicated, and the expense is so trivial as to be out of the question.

The writer yields to none in his insistence upon painstaking aseptic and antiseptic technique, particularly in major surgery, but he is profoundly convinced that the essentials of obstetric asepsis are not complicated. They consist in getting the hands clean and in keeping them so throughout the labor (this means keeping them off chairs, clothing, etc.); in refraining from such internal examinations as are not necessary; in careful external washing of the patient and in causing her to wear baked napkins during convalescence. Four simple things, if universally and carefully used to-day, would very nearly banish puerperal sepsis. They are: (1) the hand scrubbing-brush; (2) the bichloride of mercury or equivalent solution for hands and external genitals; (3) the baked (*i.e.*, sterilized) napkin; (4) the clean suit.

Four-fifths of the battle for asepsis is won when the physician will carry with him a hand scrubbing-brush, new for each case, and be willing to spend ten minutes in its use with hot water and plain soap. The best brushes may be had for five cents each; they are softer and cleaner if boiled. The bichloride solution when used after the scrubbing has tenfold cleansing power. As to the dressing, no chemicals and no elaboration are necessary. There is not a house in the land important enough to boast a bake-oven where the most perfect aseptic dressing or napkin known to surgery or obstetrics cannot be prepared in an hour by simply tearing and folding the material (the conventional old muslin is good) into proper sizes, wrapping the whole supply into a bundle covered with newspapers, and baking it in the kitchen oven one hour at such temperature as will just char the outside wrappings—that is, at a low oven heat. The nurse must be instructed to refrain from careless and unnecessary handling of these napkins, but to take them one at a time from the bundle as afterward needed. On the contrary, how often, even in good houses, does the nurse tear these napkins as

needed from old garments saved up in the closet, and apply them at once to the vulva.

Another item of importance is the clothing worn by the physician in the lying-in room. Not uncommonly does the physician find himself seated or kneeling upon the bed, during the exigencies of a labor case. Should he ever have worn a white suit he might have been surprised to find how apt it was to become stained with blood or fluids. Ordinary wearing apparel receives the same stains, but does not show them. Are there not men now wearing thus the same clothing for months with which they attend cases of erysipelas, diphtheria, scarlet fever, and indeed septic cases of labor or miscarriage? Care in changing and airing the clothing is no doubt useful and must not be omitted, but the wearing of a white duck suit drawn over the ordinary clothing, if not replacing it, is a far better measure. An excellent suit may be purchased for two dollars and seventy-five cents. Such a suit can be slipped on in three minutes, and its cleanliness will surely be appreciated by every woman, while its moral influence will not be lost on the nurse.

Lastly, let us remember the influence of the physician in setting a high standard for the nurse, and the great power he may wield for good by gradually educating his community to the better appreciation of the hygiene of the lying-in chamber. The trained nurse is to-day found only occasionally outside of large cities. The great mass of the population the country over is attended to by women without special education, who adopt the lowest standard permitted by the physicians of their community.

A few words about the comfort and convenience of a simple copper box for boiling the scissors and perineum instruments or forceps. Such a box can occasionally be found in the market, but as sold is usually too heavy or too elaborate and too expensive. It can be made by any tinman out of sheet copper, tinned on one side, at a cost of from one to two dollars. It should go easily into the bag, which it may fit along the bottom, or it may be quite narrow and shallow. The lid should go entirely inside the box for compactness in carrying, and when reversed makes an excellent tray. The boiling may be done on the kitchen stove or range. An alcohol lamp is a complication.

This paper is suggested by a need which the writer's observation has taught him exists throughout the land. It makes no attempt

at a detailed description of an ideal outfit for a consultant, or for one who wishes to make a display. It is intended as a plea for a renewed effort to grasp the essentials of asepsis on the part of the hard-worked practitioner in his every-day work. Such effort will surely be repaid in freedom from anxiety and extra labor in the after-treatment of confinement cases, in the saving of life and health and usefulness to multitudes of women.

#### TREATMENT OF ABDOMINAL CONTUSION.

Dr. EUGENE ST. JACQUES says that there are a number of means of combating shock in general and internal hemorrhages, of calming any pain present, of immobilizing the wounded region of the affected organs, the aim of all of which is to favor natural cure and to prevent complications, or to cure these complications if they should arise. Stimulants, injections of different serums, ether or caffeine, absolute rest, diet, ice internally and externally, opium in all its forms, and different medical treatment according to the indications of the morbid state, form the basis of these methods of treatment. "In the presence of a very severe shock or of a very light one, there is unanimity in regard to the means to be employed. We have succeeded in obtaining a cure in extensive tears or rents of the liver, spleen, and kidney. But agreement ceases in doubtful cases."

Among the surgeons who took part in the discussion of Dr. St. Jacques' remarks was Le Dentu, who said that, except in cases of rupture of the kidney or bladder, the direct diagnosis of visceral lesions caused by abdominal contusions is open to numerous chances of error. In doubtful cases some wish a purely medical treatment; a second class refuses surgical intervention as long as the peritoneum shows no inflammation, or as long as collapse is not imminent; another class resorts to laparotomy as soon as the symptoms appear to be in the least serious. Le Dentu holds that a purely exploratory laparotomy is justifiable whenever the diagnosis is doubtful and circumstances permit *a priori* the possibility of visceral lesions. Intervention ought to be as hasty as possible, the least hemorrhage necessitating immediate action, but in general it is well to allow the wounded patient an hour or two to recover from the violence of the initial shock.—*Medical Record*, Sept. 17, 1898.

### ANTITOXIN AND DIPHTHERIA.

The value of the antitoxin treatment in diphtheria is so universally acknowledged by the medical profession in this country that it seems unnecessary that an editorial should be written even with the purpose of emphasizing its value; yet there are still certain persons who proclaim from the house-tops that this plan does not rest upon a scientific basis, and that in practical application it fails to do that which is claimed for it. In some instances this view simply rests upon dogmatic assertions; in others it is apparently fortified by the quotation of statistics, and in no instance is this more noteworthy than in some figures which have been published by Kassowitz upon the reduction of mortality of diphtheria by means of this treatment.

When we come to study a large body of statistics dealing with the prevalence and mortality of a disease which afflicts individuals at widely distant points, it is proper that we do not lose sight of the fact that epidemic diseases vary greatly in their severity in different places and at different times, and in some instances without our being able to explain the cause of their moderation or viru-

lence. It is also true that increased hygienic learning is doing much to limit the frequency and severity of all infectious maladies, and that for this reason too much credit is not to be given to any plan of treatment until it is clearly shown that these factors which we have named have been eliminated as far as possible, and that the plan is really worthy of the credit which is claimed for it. When statistics are freed from these doubts they carry with them conviction, and Kossel has recently published some striking facts in regard to the mortality of diphtheria in Germany, which are as follows, and which indicate a marked reduction in the death-rate, due, at least in part, to antitoxin:

Year.	Absolute number of deaths from diphtheria in German towns over 15,000.	Berlin during same period.	Rate per 10,000 living.
1886.....	12,211	1662	12.4
1887.....	10,970	1302	10.7
1888.....	10,142	1195	9.6
1889.....	11,919	1210	10.8
1890.....	11,915	1601	10.5
1891.....	10,484	1006	8.4
1892.....	12,365	1342	9.7
1893.....	16,557	1037	13.0
1894.....	13,790	1416	10.1
1895.....	7,611	987	5.3
1896.....	6,262	559	4.3
1897.....	5,208	546	3.5

From this table it will be seen that in 1896 and 1897 the minimum mortality from diphtheria in Berlin was 589 and 546, whereas from 1886 to 1895 the mortality varied from 1006 to 1662. Or, again, that the rate per 10,000 persons living in 1886 was 12.4, in 1893 it was 13, and in 1894 10.1, which suddenly fell in 1895 to 5.3, in 1896 to 4.3, and in 1897 to 3.5. A similar extraordinary diminution in mortality has occurred in Paris, the mortality from this disease during the last twenty years, according to the *Annuaire Statistique de la Ville de Paris*, being as follows:

Year.	Mortality, absolute number.	Deaths per 1000 living.
1877.....	2393	12.1
1878.....	1995	9.3
1879.....	1783	8.4
1880.....	2048	9.4
1881.....	2214	9.9
1882.....	2244	10.0
1883.....	1781	8.4
1884.....	1928	8.6
1885.....	1655	7.4
1886.....	1512	6.7
1887.....	1585	7.0
1888.....	1729	7.6
1889.....	1766	7.5
1890.....	1668	7.3
1891.....	1361	5.6
1892.....	1403	5.8
1893.....	1266	5.1
1894.....	1009	4.2
1895.....	435	1.8
1896.....	444	1.8
1897.....	300	1.3

Paltauf states that these figures apply equally to the provinces of France as to the capital, and it is noteworthy that it was in these years that diphtheria antitoxin became widely employed. An additional striking fact is that while the mortality fell in this miraculous way between 1894 and 1895 in Germany and in France, it failed to so fall in Austria, where the treatment was not instituted until the following year, but as soon as it was instituted a similar decrease in mortality occurred.

It has been claimed by Kassowitz that while the capitals of Germany, France and Austria show a startling decrease in mortality, London and St. Petersburg fail to do so, and for this reason the credit should not be assigned to antitoxin, but to general conditions prevailing in the capitals named. As a matter of fact, London is an apparent and not a real contrast. To those who are acquainted with the details of these matters it is a well known fact, to use Paltauf's words, that the serum on the London market at that time was a worthless article, for he states that an English manufacturer of pharmaceutical preparations between January, 1895, and July, 1896, issued tubes of 40, 60, 100, and 130 units, with 300 from tests made of the serum as a maximum, but only two tests out of eleven gave this. Similarly poor results were obtained by another manufacturer. Further than this, much of the serum imported from Germany into London at that time was inferior in quality, and tubes said to contain 250 units only contained 225. In the case of one of these antitoxins only one experiment out of seven gave a tube containing 300 to 400 units, although each was warranted to contain 500 units, while those which were guaranteed to contain 1000 units contained not more than 875. Still further, another German house supplied in London an antitoxin which was warranted to contain 100 units, but which in experiment only gave 17.5, while those tubes sold as containing 200 units gave 30 units.

In St. Petersburg Rauchfuss estimates that the mortality has been reduced to a great degree by the use of antitoxin, and Dreier gives 526 cases treated, with a mortality of 16.3 per cent., in an epidemic, against a previous mortality of 40.3 per cent. in 1890, when no epidemic was raging. A considerable number of similar statistics are to be found in Paltauf's article, which will be found in the *Medical Press and Circular*, London, of September 28, 1898.

Kassowitz asserted that within three days

after the commencement of the antitoxin treatment large numbers died, but Paltauf shows that the greatest advantage is obtained from the serum in those who usually die within three days, which is in direct opposition to Kassowitz's view. He denies absolutely the statement of Kassowitz that the use of antitoxin increases the danger of nephritis, and, finally, he adduces evidence to show that the administration of antitoxin for the purpose of immunizing those who are exposed to diphtheria is beyond all doubt a reliable method of protection.

---

#### THE RATIONAL LIMITATIONS OF THERAPEUTIC PROCEDURES.

---

Although it is true that the ignorant and superstitious regard drugs in much the same way that an Indian regards what he calls "medicine," and seem to have an idea that drugs produce in the human body effects similar to those produced by a fetich, it is curious to note how even educated persons seem to think that medicines have the power of seeking out disease and ousting it from the body as if they were exorcising evil spirits. Few of the laity seem to appreciate the fact that drugs which are powerful enough to do good, when properly administered, may do harm if contraindications exist to their use, and this unfortunate attitude seems to be assumed now and again even by practitioners of medicine.

As a result of ignoring the proposition that that which is powerful for good may be powerful for harm, remedies are often given which not only fail to produce good results but actually do serious damage, and because members of the profession do not take time to think of the contraindications which exist they are often led into the blind following of prominent authorities, without analyzing the advice of that authority in their own minds. As a result such persons often outstrip the original prescriber in the wide scope of diseases to which they apply the therapeutic measure which he has suggested. This is true not only of drugs, but of remedial measures other than drugs, and is perhaps nowhere better shown than in the attempt which is being made by some would-be advanced physicians in the application of what has been called the Brand treatment of typhoid fever. Having read the fact that this treatment in a certain proportion of cases will very materially increase the chances

of the patient's recovery, they jump to the conclusion that it is the best treatment for all cases and entirely ignore the fact that its originator has again and again reiterated his opinion that, like all other methods of treatment, it necessarily has certain limitations. One of the most important edicts issued by Brand has been that the bath treatment is of value in direct proportion to the earliness with which it is instituted, and that there are certain conditions of the body which contraindicate its employment in the later stages of the disease.

Indeed, it may be stated that after the second week the majority of cases of typhoid fever should not be submitted to the bath, although of course there are numerous instances to be met which are exceptions to this rule. Our attention has been once more called to this important point by a paper which is published by Dr. Simon Baruch, of New York, in the *Medical Record* of October 1, and he states that while Brand believes that when cases are seen in the first stages of the disease the bath is absolutely essential to success, a large experience has convinced him that in the later stages of cases which have not in the beginning been treated by the Brand method a decided deviation from the regular plan is imperative. Dr. Baruch then goes on to quote a number of cases in which patients gravely ill of typhoid fever were brought through their illnesses, in one case by the use of the bath, and in others by a modification of the Brand method with the substitution of affusions. Thus a man of twenty-seven years, who came under treatment after thirteen days of illness in a boarding-house, and who had a pulse of 150, with dulness, apathy and murmuring delirium, tympanites and marked subsultus, and in whom the baths did not accomplish all that was desired, speedily became better under the use of cold affusions, the administration of stimulants, and proper food; and although later on in his attack baths seemed wise and did good, the case is cited as an instance of the fact that harm can be done by strict routine therapeutics. In one patient aged forty years, who had been ill six weeks and was believed to be *in articulo mortis*, the bath was not applied, but in addition to strychnine, wet compresses were applied to the chest every hour and ablutions at 70° every two hours, with the result that the patient recovered.

The object of this editorial note is primarily to point out the fact that strict routine should never be resorted to in the treatment

of disease, and conversely that a routine method established by a competent authority should not be varied unless very clear and distinct reasons can be given for such variation, and also to point out, that while a large proportion of patients will receive much benefit from cold baths, all patients do not necessarily require them.

---

#### AFTER MANY DAYS.

---

We had occasion some months ago to call attention to the fact that an article which had been originally published in our columns by Dr. Hartzell, on "The Uses of Resorcin in Dermatology," had been abstracted first in the German medical journals, then in several French journals, and finally came back to us abstracted in a well known American medical weekly, not credited to the journal that originally published it, the *THERAPEUTIC GAZETTE*, but to a French journal which had last used the abstract. Within the last week we have received a copy of the *London Clinical Journal* containing an abstract which is credited to the *St. Louis Medical and Surgical Journal*, and which that journal had credited to *La Semaine Médicale*, although the original publication on "The Use of Alcohol and Strychnine in the Treatment of Apparent Death in the New-born" was published by Dr. Bedford Brown in the *THERAPEUTIC GAZETTE* many months ago. We are glad to find that the material in our pages proves so valuable to our contemporaries, but we wish that due credit should be given to us for the original articles which we publish.

---

#### THE PRECISE VALUE OF CREOSOTE IN PULMONARY THERAPEUTICS.

---

When Sommerbrodt some years ago wrote his early papers upon the value of creosote in pulmonary tuberculosis the profession immediately jumped to the conclusion that his clinical results were correct and that the drug was one which would cure at least a certain proportion of tuberculous cases. As with many other highly vaunted remedies which have been used in this affection, it was not long before it was found that its value was limited, and while in some cases it relieved cough and aided expectoration, in others it failed to produce any marked amelioration and certainly did not materially modify the primary pulmonary lesion. At

the same time the cases have been numerous in which creosote when taken by the patient suffering from pulmonary tuberculosis has proved of very decided advantage and has so modified many of the most pressing symptoms that the clinician who has employed it has felt inclined to give it great praise, and has even noticed an improvement in the patient's general condition, this improvement being due to its useful influence in clearing the lung of secretion and in modifying cough.

Our attention has once more been directed to this matter by a brief editorial note in the *Journal of the American Medical Association* of October 20, 1898, which is entitled "Creosote not a Specific." In this note the well known and oft-repeated statement is made that our chief duty in the treatment of pulmonary tuberculosis is to maintain by every means in our power a condition of high vitality, perfect metabolism and consequent perfect nutrition, and the fact is also emphasized that creosote does not exercise an antibacillary influence, nor does it diminish the influence of the tubercle bacillus, although the writer of the editorial note recognizes, as we have already said, that it often exercises a favorable influence upon the symptoms of tubercular patients. Considerable experience in the use of creosote in tuberculosis has convinced us that it is most valuable in those cases in which there is an associated bronchitis of a chronic type characterized by profuse expectoration. In other words, the creosote acts as a stimulating expectorant by aiding in the expulsion of mucus from the bronchial areas, relieves the lung of secretion, and thereby aids the respiratory movements. On the other hand, in those cases of pulmonary lesion in which the bronchial symptoms are not marked, we have never been able to see that creosote exercised any beneficial influence. On the contrary it has seemed in many cases to disorder the digestion and thereby destroy the most powerful factor that we can call to our aid in maintaining the patient's nutrition. It ought to be recognized, therefore, that creosote is a valuable remedy for the relief of the bronchial complications of tuberculosis, and exercises but little good so far as the tubercular focus itself is concerned.

It has also been the experience of those who see many cases of tuberculosis that creosote should be used with caution or not at all in those patients who have a tendency to hemoptysis and in those who have marked febrile involvement.

#### LOCAL ANESTHESIA.

In the *Archives für Klinische Chirurgie*, 57 Band, 2 Heft, are found a series of papers on local anesthesia by means of cocaine and eucaine, which deal partly with the chemistry and physiology of these drugs, but mainly with their practical application, and which show, among other things, that their use is, in Germany, far more common than it is with us, and that even for major operations, such as the radical cure of hernia and gastro-enterostomy, local anesthesia is successfully and by some surgeons habitually employed.

In comparing cocaine and eucaine from the standpoint of their practical applicability, Braun has proven by an experimental research that when used in equal strengths they are about equal in their anesthetizing effects and power of diffusion. Eucaine is, however, decidedly less irritating to the tissues, hence causes less primary pain, can be boiled without having its chemical composition altered, and is not more than one-half as toxic as cocaine. Any one of these advantages would entitle it to first choice.

The addition of sodium chloride is for the purpose of making an osmotically indifferent solution, which producing no reaction on the tissues allows the anesthetic contained to exert its full specific effect upon the nerve filaments. Hence, instead of using .2 per cent. of salt Braun employs .8 per cent. The morphine, an ingredient of Schleich's solution, he rejects entirely, holding, and with justice, that it is a local irritant, that it can in no way augment the local anesthesia, that it increases subsequent edema, and that if it relieves the pain which is felt as the anesthesia passes off it can do this only by a systemic and not by a local action, in which case it is evidently better to employ the morphine as an injection in some region other than that subject to a surgical operation. The solution Braun uses, probably the least immediately painful, the safest, and the most efficient yet advised, is as follows:

Eucaine B, gr. j;  
Sodium chloride, gr. viij;  
Distilled water, f ʒ ij.

This keeps well and can be boiled an indefinite number of times without deteriorating. It should be at about blood heat when injected. It is osmotically indifferent, causes no irritation, and produces an anesthesia which lasts from ten minutes to an hour, in accordance with the quantity injected,

the vascularity of the part, and the mechanical possibility of producing blood stasis in it. The methods of employing the anesthetic solution are: by infiltration, first of the skin, then of the deeper tissues, as elaborated by Schleich; by circumferentiation—*i.e.*, surrounding the area to be operated on by a ring of skin and subcutaneous injections; by injections close to the nerve trunk supplying the region to be operated on, as fully described by Oberst and Pernice, and termed by them regional anesthesia.

The infiltration method is open to the objections that it prolongs an operation and that it so alters tissues that there may be difficulty in distinguishing between the pathological and normal; moreover, the injection is in itself extremely painful if driven into an area acutely inflamed, and may carry pathogenic germs directly into blood-vessels. It is therefore not well adapted to operations in which fine dissection and the recognition of structures and tissues are essential, as for instance the removal of the deep glands of the neck, or the modern excision of a cancerous breast, or even the radical cure of hernia. It is, however, admirably suited for operations involving the skin, such as the removal of papillomata or epitheliomata, or the excision of nails; or for the removal of superficial and sharply circumscribed growths, such as fibromata or lipomata; or for circumcision, but in this case both the skin and mucous surfaces of the foreskin must be infiltrated along the line of incision; or for such operations as vasectomy or suprapubic cystotomy, or exploratory laparotomy, or tapping of hydrocele, or excision of veins, or exploration for the removal of foreign bodies.

The circumferential method finds its application in cases in which the surgical procedure is limited to the skin and subcutaneous tissues, and is also useful in operations on the fingers and toes, the injection being driven into healthy tissue, close to the proposed seat of operation and completely surrounding the member, a constricting band being first placed on the proximal side of the area selected for injection, having for its object the stopping of the circulation.

The regional method has at present its principal application in operations for felons and amputations of the fingers and toes; a one-per-cent. eucaïne solution is used for these injections, and is driven in close to the nerve trunks toward the base of the

digit, a rubber band being first placed above the latter.

Gottstein states that of ten stomach resections practised in the Breslau clinic in the last year eight were done under cocaine. Some of these operations lasted over five hours. There were also seventeen gastroenterostomies, four pyloroplasties, nine exploratory laparotomies, fifty gastrostomies, six goitre resections, and a great variety of other operations. An observation made by Gottstein is of especial interest and importance. He states that one reason for the adoption of local anesthesia was based on the hope that the post-operative lung complications so common after the use of chloroform and ether might thereby be avoided. In this hope he was disappointed; pneumonia and bronchitis developed about as frequently after belly operations as when general anesthetics were used.

Mikulicz performed two hundred and thirty-four operations on two hundred and twelve patients, using local anesthesia. One hundred and thirty-eight of these patients were subjected to abdominal operations; observations on one hundred and fourteen showed that twenty-seven (twenty-four per cent.) suffered from post-operative pulmonitis. The abdominal cases operated on under chloroform and ether show not more than five per cent. of post-operative pulmonitis. Since cocaine was used, and often in its maximum dose, it seems not unreasonable to suppose that there resulted therefrom a crippling of the circulation which strongly favored congestion of the lungs. It should be stated that the cases operated on under cocaine were the most advanced and most difficult and were often so devitalized that operation under a general anesthetic would not even have been attempted.

For the painless induction of local anesthesia a fine, very sharp needle is required; this should be driven into healthy tissue. After the first drop of warm solution is injected there should be no further pain.

The rough handling of the peritoneum often causes intolerable anguish; this in itself is likely to prevent the general use of local anesthesia in abdominal surgery. There are, however, thousands of operations for the performance of which ether or chloroform is given which could be made absolutely painless by eucaïne injections, and it is to be hoped that this procedure will receive the general adoption which its safety and simplicity warrant.

## Reports on Therapeutic Progress

### *THERAPEUTIC SALINE SOLUTIONS AND THEIR USES.*

We have so often urged upon the readers of the *GAZETTE* the importance of hypodermoclysis and of intravenous injection that we quote with pleasure a paper by S. S. COHEN in the *Philadelphia Polyclinic* of October 15, 1898. Dr. Cohen wishes to call attention to a measure that has been practised by a few physicians for many years, but has recently come into great vogue, and he hopes it will be used by physicians more and more. He refers to the introduction under the skin (hypodermoclysis) or into the veins (venous infusion) of a solution which in chemical composition, specific gravity and temperature nearly approaches the inorganic portion of the blood-serum. It is sometimes erroneously called "normal salt solution"—a meaningless term. In chemical nomenclature a "normal solution" of any reagent is one that contains in a liter exactly enough of the given substance to combine with, or replace in combination, one gramme of hydrogen. "Salt" is a class term and does not indicate any particular substance. "Physiologic salt solution" or "physiologic saline solution" is (approximately) a decinormal solution, one-tenth the strength of "normal solution," of sodium chloride. It is called "physiologic" from its use in investigations upon the blood in the physiological laboratory. Solutions of sodium chloride containing 0.65 to 0.75 per cent. of that salt preserve the blood-corpuscles from shriveling when withdrawn from the veins, and do not bring about their disintegration. The total percentage of saline constituents and the proportions of the several salts contained in normal blood are variously stated by different observers. Of sodium chloride there is about 0.5 per cent., and of other sodium salts (sulphate, carbonate and phosphate) about 0.1 per cent. additional; potassium, calcium and magnesium salts bring up the total to a figure given by one observer at 0.645 per cent., and by others as high as 0.9 per cent.

The therapeutic saline solution cannot therefore be made to comply with an ideal or even average standard of blood-serum composition; and to insist upon a definite percentage and constitution is, in the present state of knowledge, useless pedantry. For most purposes a solution of sodium chloride will answer, and the convenient proportion

of a drachm to the pint (or its approximate equivalent of eight grammes to the liter) is easily remembered, and sufficiently accurate.

In cases of threatened or actual diabetic coma, or in any other condition in which it is deemed necessary to alkalinize the blood, sodium carbonate may be substituted for a portion of the sodium chloride; and the writer has found one-third of the total saline strength a convenient and safe proportion of this agent when used by the subcutaneous method.

Dr. Locke, of Boston, and Dr. H. A. Hare have suggested a general formula for "artificial serum," which contains in the liter:

Calcium chloride, 0.25 gramme;  
Potassium chloride, 0.1 gramme;  
Sodium chloride, 9.0 grammes.

It is extremely important, whatever formula be employed, that the solution and all the apparatus used be properly sterilized. In an emergency, in any household, a teaspoonful of sodium chloride may be dissolved in a pint of tap water, and the solution sterilized by boiling. If the water contains foreign particles that cannot be strained out, and there is no proper filter at hand, the water must be allowed to stand, after boiling, until sedimentation occurs, when the supernatant fluid should be poured off, again sterilized, and used. When time permits, distilled water, filtered water, or other prepared clear water should be used for the solution. One may sometimes find Poland water, which contains very little mineral matter, useful and handy.

The therapeutic saline solution—as Cohen prefers to call it, thus avoiding the misleading terms "physiologic" and "normal"—should be introduced at a temperature of about 38° C. or 100° F.; and if the process is slow care should be taken to maintain the heat meanwhile. It may then be introduced directly into a vein (a process often erroneously termed "transfusion," but properly called "venous infusion"); or it may be introduced into the circulation indirectly through the absorbents beneath the skin ("subcutaneous infusion" or "hypodermoclysis"); or it may be introduced into the peritoneal sac ("peritoneal infusion"); or it may be introduced into the intestine ("enteroclysis"). Subcutaneous infusion is the usual and most convenient method. Venous infusion is resorted to when time is a prime object; or peritoneal infusion, as especially advocated by Sir B. W. Richardson in the collapse of cholera, may be employed when

subcutaneous infusion is too slow, and the venous method dangerous or inexpedient.

Enteroclysis may be used when time is not at all pressing, and one desires to avoid puncturing the skin. It is uncertain, but often efficacious. The writer's own resort to the therapeutic saline solution is becoming more and more frequent; and he has used all the methods mentioned, except that by the peritoneum. Venous infusion, however, he is now less inclined to resort to, excepting under distinct stress of urgency, as the hypodermoclysis is reasonably prompt; and, indeed, for one who is neither a surgeon nor a physiologic investigator, unfamiliarity with the manipulations of venous infusion—comparatively simple as they are—may act as a deterrent, or induce greater delay while skilled assistance is being sought than the difference between the methods as to the rapidity of absorption.

#### *TAPPING AND VENESECTION IN NEPHRITIS AND UREMIA.*

At the recent meeting of the British Medical Association EWALD, of Berlin, contributed to the Section on Pharmacology and Therapeutics a practical paper on this subject. After pointing out that it is a well known fact that the question as to how diuretics act in kidney diseases is not yet settled, and that some still believe that their action is due to increased blood-pressure, or to some relief of the circulation through the kidneys, most authorities at the present time are of the opinion that they act by direct irritation of the secretory elements of the kidneys. However this may be, this much is certain, that the effect of the heightened diuresis or the diversion of fluid to the intestinal canal, provided of course it succeeds by internal medication, is to cause but very slow absorption of fluid in edematous tissues or in the peritoneal cavity or other serous spaces. On the other hand, practical experience teaches us that diuresis always increases as the decrease of fluid in the subcutaneous tissues and in the serous cavities progresses.

Physicians have always tried to dispose of these transudates by mechanical means. From the various serous cavities the fluid is withdrawn as much as possible by puncture. From the subcutaneous tissue it is withdrawn by means of diaphoresis, by hot baths, by scarification, and by puncture with small needles (Southey, Gerhardt, Curschmann, and others). In the writer's opinion, how-

ever, the treatment by none of these methods is carried out energetically enough, and the scarifications and removal by puncture with small needles are not complete enough; and secondly, they have too many inconveniences attached to them.

Puncture for ascites and pleurisy is done too seldom—that is, the physician waits until a considerable amount of fluid has collected. Several weeks is allowed to elapse between the punctures, and in the meantime the organism is exposed to all the dangers, local and general, that a collection of fluid in a serous cavity brings with it. The spontaneous resorption of the fluid is rendered extremely difficult by the pressure exerted upon the blood and lymph vessels of the pleura and peritoneum by the presence of the fluid. The endothelium of the serous membrane suffers in time in its nutrition. The organs contained in these cavities are more and more compressed and their function is disturbed.

These are sufficient grounds to justify the making of punctures in such cases as often as the slightest indication presents itself. To this it is objected that experience shows that transudates removed by puncture are renewed very rapidly, and some have even believed that their removal of itself constituted an irritation sufficient to lead to their rapid renewal. It has been thought, too, that the removal of a transudate deprived the organism of an important amount of albumen. Neither of these objections holds. The albumen in such cases is in a form in which it cannot be of use for organic metabolism, and it is in such small quantities that its loss, as the author showed years ago, cannot be of the slightest importance. As to the renewal of the fluid, that is due to the course of the disease, not to the puncture for its removal. When the affection grows better the repeated punctures cease, and they have had an important influence for good.

In such cases the author punctures and withdraws the fluid that has collected as often as enough has accumulated to make puncture fruitful—that is, under some circumstances every third or fourth day—and with excellent results. He is convinced that he has by this means, and the proper treatment of the edema, brought about the cure of nephritis in a number of cases.

The drainage of the edema the author effects by means of long needles such as are used for tapping the pleura. They are inserted into the subcutaneous tissue, as far as

possible parallel to the skin, and the part that projects is covered with a layer of salicylic cotton and iodoform collodion. To the end of the cannula a rubber tube is attached that hangs down alongside the bed, in a vessel placed to receive the fluid that trickles through the tube. By means of a safety-pin the rubber tube is fixed on the mattress and not allowed to pull upon the needle persistently. Into each leg one or more needles are inserted, and it is thus possible to withdraw three to five liters of a clear, amber-colored fluid in a day. As the subcutaneous areolar tissue is everywhere freely in communication with other parts, the fluid is withdrawn not alone from the legs but from the abdominal walls and the scrotum as well. As because of the edema the limbs are heavy and difficult to move, it is not difficult to keep the patients quiet in that position best calculated to favor the outflow of the fluid.

Of course, these manipulations must be carried out under the strictest antiseptic precautions. Erysipelas, gangrene, or any other serious accident, the author has never seen except in one case. Erythematous conditions sometimes set in, but disappear promptly under an alcohol bandage. This procedure has these advantages over scarification: it is much more cleanly, does not cause the skin to be soaked with edema fluid for long periods, and much larger quantities of fluid are removed with less inconvenience. In this way he has in a single case of chronic nephritis, from September 10 to December 3, 1896, removed 22,500 cubic centimeters of fluid, and during the period from October 6, 1896, to March 13, 1897, 140,000 cubic centimeters of ascitic fluid in forty punctures. During December and January a puncture was made about every third day. Four punctures of the pleural cavity were made and fifteen liters of fluid removed. The result was complete disappearance of the anasarca and complete recovery of the patient.

Ewald remarks in concluding that repeated careful estimations of the albumen in the ascitic fluid showed that it was between 0.6 and 0.75 per cent., and the amount of albumen thus removed then was equal to about 3136 grammes of meat.

The symptoms of uremic intoxication present, as is well known, a most varied picture. They may occur in acute or chronic form, from slight headache and nausea (gastric catarrh) to uncontrollable vomiting and diar-

rrhea, from nervous unrest and a feeling of anxiety to the severest epileptiform attacks, from the lowest grade of benumbed sensation up to deepest coma. They may present themselves in varying forms. They may appear under the form of chronic insanity, or of periodic attacks of confusional insanity, or as light attacks of delirium, or may simulate asthma, angina pectoris, or cardiac asthma; they may be complicated by hemiplegia or monoplegia, anesthesia, slight paresis, attacks of vertigo, nose-bleeding, or disturbances of sight or hearing, etc.

There is manifestly always question of an autointoxication—that is, of a toxic effect of products in the circulation which should have been excreted by the kidneys. May not these products give a direct irritation or act indirectly by augmentation of the blood-pressure? Nothing would seem more feasible and more likely to be of benefit than to withdraw a portion of the blood and so decrease the absolute amount of toxin and make the blood more watery, especially if the physician infuses, as does von Leube, after the venesection a certain quantity of physiological salt water. Medical men have, in the author's opinion, in recent times neglected venesection too much in such cases. Long ago Archibald Pitcairn (1713) recommended venesection.

Bartels got excellent results from venesection in cutting short acute attacks of uremia. Krönig and Senator have recommended it after personal experience in recent years. The author is far from saying that venesection ought to be done in every case. But when the strength of the patient will permit it, and where the conditions of the heart do not prevent it, as soon as the other well known remedies have no quick effect he should be treated without delay by plenteous blood-letting—that is, by the abstraction of 200 to 400 grammes of blood. In future he will combine with the bleeding an infusion of saline water, as von Leube recommends.

A few years ago Jacobi, of New York, introduced in medical literature the words of warning, *Nil nocere* (Be sure you do no harm), and they have met with universal approval. But by venesection under such circumstances we can never do harm. The proportion of permanent success of this method of treatment has, in the writer's cases, been equal to 62½ per cent. of the occasions on which it has been employed. That furnishes ground enough, to his mind, to justify him in recommending the employment of venesection in uremia.

*THE PHYSIOLOGICAL ACTION OF HYDRASTINE HYDROCHLORATE.*

PHILLIPS and PEMBREY contribute to the *British Medical Journal* of October 8, 1898, a paper with this title. They begin their paper by telling us that *hydrastis canadensis*, yellow root or golden-seal, is a small herbaceous perennial, indigenous to most parts of the United States and Canada; and that it belongs to the Ranunculaceæ. In the rhizome of the plants are contained the following active principles: hydrastine, berberine, and canadine; in addition to sugar, albumen, and extractives, there is a resin and a small quantity of an ethereal oil. Hydrastine is a derivative of isoquinoline, and its formula, according to Freund and Will, is  $C_{15}H_{11}NO_6$ . It was first isolated by Durand in 1851.

In their experiments pure hydrochlorate of hydrastine was used on account of its solubility in water. A few experiments were made with pure hydrastine and with fluid extract of hydrastis; but on account of the insolubility of the former and the presence of alcohol and other substances in the latter, the results were unsatisfactory. The method of administration of the hydrochlorate was by subcutaneous injection of aqueous solutions.

In frogs 20 decimilligrammes ( $\frac{1}{5}$  grain) caused within twenty minutes paralysis of the fore limbs, succeeded in a minute or two by spasms similar to those produced by strychnine; the frog recovered by the next day. A dose of 81 decimilligrammes ( $\frac{1}{3}$  grain) caused convulsions within fifteen minutes; the body during a spasm was rigid, and rested on the mouth and toes of the hind limbs. Death generally occurred within two hours.

In mice a similar dose to the last produced convulsions within fifteen minutes, and death within half an hour. A dose of 486 decimilligrammes ( $\frac{2}{3}$  grain) had apparently no effect upon rats, but double that amount caused within twenty minutes paralysis of the hind legs, succeeded within half an hour by convulsions, and by death within three hours. A dose of 0.1296 gramme (2 grains) quickened these stages and caused more marked convulsions, together with salivation.

In rabbits no effect beyond a quickening of respiration and increased liveliness was produced by a dose of 0.7776 gramme (12 grains). In the case of a half-grown rabbit 11.5 grammes (15½ to 23 grains) caused convulsions within twenty minutes; the head was thrown back and the legs extended; tonus

and clonus were well marked, and death occurred within an hour and a half.

The cat is much more susceptible to the action of the drug than is the rabbit. A dose of 0.6480 gramme (10 grains) produced a very profuse salivation, commencing within thirty minutes of the injection; the respiration was very rapid, and there was considerable depression. In all cases there was marked loss of appetite, widely dilated pupils, slight spasms, and incoordination; in some there was also vomiting. Death followed convulsions in one case—a strong, full-grown male—on the second day after a dose of one gramme (15.4 grains).

Three or four frogs after showing typical convulsions recovered when kept in moist surroundings; one frog remained apparently well for five days, but on the sixth day was again seized with convulsions and died.

A kitten two days old recovered after spasms produced by a subcutaneous injection of 108 decimilligrammes ( $\frac{1}{4}$  grain) of the drug.

The direct application of two or three drops of a solution containing one part of hydrastine hydrochlorate in 200 parts of tap water produced a marked effect upon the heart of a frog. The rate of the contraction was diminished, but the force and duration were augmented; thus in one case there were two contractions in fifteen seconds as compared with two in four seconds before the application of the drug, and the duration and force of the ventricular contraction were more than doubled.

After the application of a few drops of the solution (1 in 200) to the sinus of the frog's heart, strong faradic excitation of the vagosympathetic produced no inhibition. Stimulation of the crescentic groove, however, stopped the contraction of the heart. The effect of the drug was chiefly upon the sinuauricular junction. Thus, if the contractions of the auricles and ventricle were separately recorded, no appreciable effect was observed if the surface of the ventricle, or of the auricles, was painted with the solution of the drug. The application, however, of the solution to the sinuauricular junction quickly produced a slower and more powerful beat of the ventricle and auricles; finally these ceased to beat and the sinus alone continued to pulsate.

The action of the vagus was also suspended in mammals by the direct application of the drug to the heart. Thus stimulation of the vagi did not stop the contraction of a rabbit's

heart after the injection of ten minims of 1-in-200 tap water at 37° into the pericardial sac. Before the injection a much weaker stimulation readily produced inhibition.

The drug produced contraction of the arterioles, but this effect appeared to be brought about chiefly through the nervous system. There was, however, some local action, as shown by the application to an inflamed conjunctiva of a solution containing one part of hydrastine hydrochlorate in 200 parts of tap water.

It has already been mentioned that poisonous doses of the drug produce convulsions similar to those caused by strychnine. In frogs the cutaneous sensibility is so much increased that a slight touch or puff of wind suffices to send the frog into convulsions. The convulsions are of central origin, for section of the nerves abolishes them. The rate of contraction of the muscle is from eight to ten per second. The tonic contractions are followed by well marked clonus. In some cases the drug first causes partial paralysis, but this in most cases appears to be due to the local action of the drug around the seat of injection. Thus in a rat the left hind limb was paralyzed for motion and sensation after the injection of two grains of the drug dissolved in 15 minims of tap water. This limb was not so much involved as the others when later the body was convulsed. They observed in cats that the pupils were stationary at first, then widely dilated, and even more so the day after the injection of ten grains of the drug.

The direct application to the frog's nerve and muscle of a solution containing one part of the drug in 1000 parts of tap water had apparently no effect upon their excitability. A stronger solution, 1 in 200, appeared to act first upon the nerve endings and then upon the muscle. A gastrocnemius muscle placed in a watch-glass containing such a solution failed to respond to stimulation of the sciatic nerve, which was outside of the liquid, but contracted on direct stimulation. Soon the muscle became more opaque in appearance and quite inexcitable.

In both warm-blooded and cold-blooded animals fatal doses of the drug caused respiration to cease some time before the failure of the heart's action.

No effect was observed upon the digestive system of the rabbit and rat, but in the cat there was marked salivation, vomiting, and loss of appetite for several days after a large dose of the drug. In one cat, which died

after receiving one gramme (15 grains), there was no gastric inflammation, but much bile in the gall-bladder and bile-stained liquid in the stomach and upper part of the small intestine.

The saliva collected within fifteen minutes and twenty-five minutes of the injection of 0.648 gramme (10 grains) of the drug into a cat produced fatal results in frogs; the quantity of saliva injected hypodermically was fifteen and twenty minims respectively.

The drug is rapidly excreted by the kidneys, for the authors found that the urine passed within twenty-five minutes of the injection of 0.648 gramme (10 grains) into a cat produced typical convulsions in a frog, but a toxic quantity was still discharged on the second and third day. Normal urine when injected into a frog produced no effect.

Pregnant rats and rabbits did not abort even after receiving large doses of the drug, but one cat aborted twelve days after a hypodermic injection of one gramme (15.4 grains), a second cat four days after, and a third cat twelve hours after a dose of 0.6480 gramme (10 grains). The fetuses in each case showed no sign of life, and there is little doubt that they were killed by the drug before abortion commenced. The difference between the results in the case of the rabbits, rats, and cats is to be attributed to the marked susceptibility of cats to the action of the drug. The liquor amnii was found by experiments on frogs to contain poisonous doses of the drug.

Experiments upon rabbits and cats failed to show any action of the drug in producing contraction of the muscle fibers of the uterus.

Rigor mortis comes on exceedingly quickly after death from poisonous doses of the drug, in some cases even within a minute or two of death. The rigidity is so marked that it was possible to hold the dead body of a cat upright by grasping one of its hind limbs.

The following conditions were observed: Marked distention of the right side of the heart, congestion of the pia mater, and an abnormally large quantity of bile.

Weak solutions, 1 in 1000, quickly produced the disintegration of infusoria, and putrefaction was delayed or suspended in the bodies of animals poisoned by the drug.

#### THE TREATMENT OF ENTERIC FEVER.

WALGIER (*Centralblatt für Innere Medizin*, Sept. 19, 1898) discusses the treatment of this disease with the serum obtained from convalescents. He relates in detail four

cases so treated. All four patients presented an unfavorable prognosis before the injection was given. Cases 1 and 2 occurred in decrepit and poor women, whereas the third case, in a strong, healthy young woman, was of a severe type. In Cases 1 and 2 the general condition improved rapidly after the injection. In Cases 3 and 4 the disease lasted longer, but here also the good effects of the injection were very obvious. The author remarks that under this serum treatment the anatomical process may gradually recede, or it may continue for some time, or even perhaps spread. In Cases 3 and 4 relapse occurred, but the author thinks that if they had not been injected they would probably have died. The repetition of the injection in the one attack has, in the author's opinion, no object, but it is different in the relapse, which he looks upon as a fresh attack. The amount of serum injected was ten cubic centimeters. Walgie apparently thinks that the use of an efficient serum treatment will render Widal's test unnecessary.—*British Medical Journal*, Oct. 8, 1898.

A DISCUSSION ON THE THERAPEUTIC  
VALUE OF RECENT SYNTHETIC  
ANALGESICS: THEIR BENEFITS  
AND ATTENDANT RISKS.

In the *British Medical Journal* of October 8, 1898, STOCKMAN, of Glasgow, writes on this topic.

In opening this discussion the speaker stated that he was at the outset confronted by two difficulties, the first of these being the very large number of substances with which he should have to deal if he made the attempt to overtake all the synthetic analgesics brought forward during recent years, and the second being that Dr. Lockhart Gillespie enjoined him to compress his remarks within the space of twenty minutes. Under these circumstances it was quite impossible for him to do more than glance briefly at a few of the more important analgesics, and to touch on their more salient characteristics. This is to some extent an advantage, as, as he said, he could not pretend to have a practical clinical knowledge of the relative value and defects of more than a small number of these substances, for as it requires long and careful observation to become thoroughly acquainted with the possibilities and best modes of using even the most commonly employed medicinal remedies, so in practise he has confined his clinical observations to a

small number of analgesics only. Most of them have been introduced not so much in the character of analgesics as in that of antipyretics, but at the present time, and speaking very generally, their employment to reduce temperature has assumed less importance than their value in reducing pain. This is due very largely to the fact that the direct antipyretic treatment of feverish conditions has to a great extent gone out of fashion owing to the more specific treatment by means of serum antitoxins, which at present is receiving such a wide trial.

Long experience has now demonstrated very clearly that the administration of medicines which—so far as we know, at least—merely reduce temperature has comparatively little beneficial effect on the course of a continued fever, such as typhoid, and as a routine method of treatment they have been practically abandoned. On the other hand, their combined power of reducing temperature and of relieving the pain and discomfort consequent on fever make them of great practical value in certain diseases accompanied by marked pyrexia. From the author's own experience he mentions two of these especially—namely, acute rheumatism and malaria—where the combination of an analgesic and antipyretics, such as phenacetine, with the more specific remedies, salicylates and quinine respectively, conduces very greatly to the comfort of the patient, if not to a direct cure of the disease. It is, however, more directly with their value as analgesics that we are concerned to day.

At the outset the author states his opinion that no one of them hitherto tried acts in an ideal way, either in reducing temperature or in relieving pain, and that no one is without more or less serious drawbacks for general and frequent use in practise, although he is inclined to think that their dangerous effects have been greatly exaggerated. Both their remedial and poisonous actions can be best and most clearly studied by briefly tracing their chemical genealogy, when we shall see that all of them are closely related, both chemically and in their effects, to the well known substance phenol, and to a body very nearly allied to it, anilin. By chemical modification of these bodies and their derivatives changes in action can be brought about in certain directions, our efforts being directed to lessen their toxicity and to increase their analgesic action. Unfortunately our studies as to the relationship between chemical constitution and physiological action have not

yet led us to such a wide and comprehensive grasp of the subject as to enable us to prophesy beforehand what will be the result of any given alteration; hence each new aspirant for therapeutic favor has to undergo a long and tedious experimental trial before its ultimate value can be determined.

To illustrate the close chemical relationship of these substances, and for easy reference as we go along, the author has put up a table of their structural formulæ, from which it will be seen that their relationship to phenol is always more or less a close one:

$C_6H_5OH$ .....	Phenol.
$C_6H_5COOH$ .....	Benzoic acid.
$C_6H_4(OH).COOH$ .....	Salicylic acid.
$C_6H_5NH_2$ .....	Anilin.
$C_6H_5N \begin{cases} /H \\ \backslash CO.CH_3 \end{cases}$ .....	Acetanilid, antifebrin.
$C_6H_5N \begin{cases} /CH_3 \\ \backslash COCH_3 \end{cases}$ .....	Methylacetanilid, exalgin.
	Acetyl-, benzoyl-, salicyl-acetanilid.
$C_6H_4 \begin{cases} /OC_2H_5 \\ \backslash NH.COCH_3 \end{cases}$ .....	$\left\{ \begin{array}{l} \text{Ethoxyacetanilid, acet-} \\ \text{phenetid.} \\ \text{Phenacetin.} \end{array} \right.$
$C_6H_4 \begin{cases} /OC_2H_5 \\ \backslash NH.C_6H_5O_2 \end{cases}$ .....	$\left\{ \begin{array}{l} \text{Lactyl phenetid.} \\ \text{Lactophenin.} \end{array} \right.$
$C_6H_4 \begin{cases} /OC_2H_5 \\ \backslash NH.COCH_3NH_2 \end{cases}$ .....	$\left\{ \begin{array}{l} \text{Amidophenacetin.} \\ \text{Phenocoll.} \end{array} \right.$
$C_6H_5HN.NH_2$ .....	Phenylhydrazin.
$C_6H_5HN.NH.COCH_3$ .....	$\left\{ \begin{array}{l} \text{Pyrodin.} \\ \text{Acetylphenylhydrazin.} \end{array} \right.$
$C_6H_5N \begin{cases} /H \\ \backslash N=C_6H_5O_2 \end{cases}$ .....	Antithermin.

Phenylhydrazin is formed from anilin.

By heating together phenylhydrazin and aceto-acetic ether, and treating them with methyl iodide, antipyrin is formed.

There are numerous other analgesic bodies formed in the same way by ringing the changes on the various kernels, but it is not necessary to go into them further, as we see that all these substances are closely allied chemically, and there is little difficulty in tracing also their close affinity in action. In the doses ordinarily given phenol exercises little effect on the nervous system or blood, but when these doses are exceeded the cord and brain are greatly depressed by it, leading to stupor and the abolition of reflexes, while the blood-corpuscles are broken down, the temperature falls to an alarming degree, and excessive sweating occurs, effects which can be traced all through the series.

In salicylic acid the toxicity has been greatly lessened, but large doses produce cutaneous anesthesia in the dog, with ataxic gait and stupor; while none of us are unaware in man of the skin eruptions, excessive sweating, depression of the heart and anemia, which are apt to follow on its therapeutical use. Its analgesic effects in acute rheumatism are also well known.

When we come to consider the anilin we find that its action is such as to make its medicinal use highly dangerous. It is a very powerful depressant of the nervous system, causing stupor and general depression, but its most remarkable effect is on the blood, where such changes are wrought in the hemoglobin as to cause marked cyanosis of the skin and severe dyspnea.

Phenylhydrazin has also a most destructive effect on the red blood-corpuscles, and converts their hemoglobin into methemoglobin, besides causing thrombosis and marked changes in the kidney. So much is this the case, that any combination of it which is not a very firm one tends to be extremely poisonous, and on this account two of the substances already mentioned, namely, pyrodin and antithermin, are to be reckoned as poisonous rather than as therapeutical agents in practise.

Coming now to derivatives of these substances, which have been so modified chemically as to bring into prominence their beneficial effects and to diminish their poisonous actions, we find that all of them have substantially the same kind of action. This consists essentially in an action on the gray matter of the spinal cord, by virtue of which the conduction of painful impressions from the periphery is rendered more difficult. At the same time the perceptive activity of the gray matter of the cerebrum is slightly but not very visibly depressed, and no doubt the perception of impressions is to a certain degree lessened. It is on these actions that their analgesic power depends. Motor power and conduction are affected at the same time, but to a much less degree, while the brain retains its ordinary acuteness; hence the person, while obtaining alleviation from pain, is able to go about and perform his ordinary business, and herein lies the great practical utility and value of this class of analgesics.

Looking at our requirements as physicians, we need two analgesic substances having somewhat different degrees of action, one which will exert its effects on the pain-

conducting paths in the cord, leaving the remainder of the nervous system intact or nearly so, and another which in addition will exert a hypnotic or gently narcotic action on the cerebrum. One such drug would suffice if the difference in effect could be obtained by graduating the dose. Now it would be too much to expect that substances having such a pronounced action on the nervous system as these newer analgesics have should not occasionally cause unpleasant symptoms by manifesting too great an activity in certain directions, leading to undesired, and sometimes alarming, results. It would be wonderful if it were not so, for drugs, like men, have the defects of their qualities. Thus we find that their depressing effect on the medullary centers may lead to respiratory and cardiac embarrassment; their action on the vasomotor center may cause sudden dilatation of the blood-vessels, with consequent faintness or syncope, while a continual dilatation leads to severe sweating, edema, and eruptions on the skin and mucous membranes. Any great depression or collapse from an action on the nervous system is extremely rare, and probably has only occurred in persons greatly reduced by disease. We shall never get an analgesic substance quite free from the risk of causing such slight accidents and inconveniences, because these are simply exaggerations of the action which we wish it to produce on the nervous system, and it is quite impossible that we can accurately foretell the exact degree of sensitiveness of a patient's nervous system to such drugs. This varies not only in individuals but in the same person at different times. The most we can hope to accomplish in this direction is to diminish the chance of such inconvenience by using a drug which is not too active, so that by increasing the margin of dosage we may at the same time increase the margin of safety.

On the other hand, it is a very different matter when we come to consider the action of these substances on the hemoglobin and their effects in causing disintegration of the red blood-corpuscles and anemia. These must be uncompromisingly regarded as drawbacks to their use, for they subserve no useful purpose, and have no bearing on their action as analgesics. Fortunately many of these drugs have this effect only in a subordinate degree, and in ordinary doses and under favorable conditions never manifest it.

Owing to this action being so pronounced in the case of acetanilid, the author has given

up its use entirely for years past, and all the more willingly because the smallness of its dose easily allows one to overstep the margin of complete safety. Antipyrin is very much safer, and on the whole acts well as an analgesic, but it is seldom used now by the writer, who is convinced that phenacetine is equally powerful and at the same time much less apt to be attended by occasional disagreeable consequences. The only other member of the series in which he places equal confidence as an analgesic is lactophenin, a substance practically identical in constitution with it. He has never seen any unpleasant results of any kind from either of these, although he is aware that a few such cases have been reported.

In conclusion, the author states his opinion that if given with care and in suitable cases ill effects are extremely infrequent. Their value, however, is limited by the fact that they do not subdue very severe pain.

Dr. Phillips said he submitted that salophen, phenocoll hydrochloride, apolysin and methylene blue are substances of high therapeutic value, and without attempting to arrange them in order would single out salophen as of exceptional promise; that agathin, being slow, unreliable, and even dangerous in its action, should be avoided; that some hesitation should be exercised in employing analgene and citrophen because of their toxic action on the blood, in using euphorin and lactophenin because of their inconstancy and tendency to produce collapse, and in choosing malakin because of its tardy action; and that pyoktanin, ferripyrin, pyramidon, salipyrin, tolipyryrin, tolisall, and even salocoll, although they may be well and safely used as substitutes for better remedies, are unnecessary.

---

#### A PRELIMINARY NOTE ON THE PHARMACOLOGICAL ACTION OF *STIPA VIRIDULA*.

GILLESPIE contributes to the *British Medical Journal* of October 8, 1898, a valuable pharmacological study of this American plant. He tells us that in some parts of the United States, especially in those which lie further south, travelers on horseback or cowboys driving herds of cattle from one place to another over the higher prairie regions are often astonished and put to no little inconvenience when they wake some morning in the encampment chosen for the night's rest to find their horses, and maybe their cattle, unfit to proceed on the journey. They,

should the facts be new to them, imagine at once that the animals showing signs of indisposition have been poisoned; indeed, the severity of the symptoms is often so great that speedy fatal results are generally apprehended.

The traveler's horse is a pitiable object. He stands with head and tail drooping, his form quivering, streams of sweat pouring down his sides, his respiratory movements hurried and panting, his heart's action increased in force, judging by the evidence of palpation; while his excretion of urine is markedly increased, with symptoms of irritation and strangury accompanying its expulsion. The animal is incapable of movement. He appears about to die. As far as the writer's informant could say, no death, however, either in horses or cattle, is known to have actually been caused by the grass, for all these symptoms follow ingestion of a rare grass, the *Stipa viridula*, growing in scattered bunches over the elevated prairies in New Mexico and Texas.

The facts given above have been derived from descriptions of the effects as personally studied by an acute observer who has lived for some years in the country mentioned, and who, indeed, presented the writer with the grass whose virtues he is investigating.

The plant grows in clumps or bunches of closely - applied, tall, elegant stems, surmounted by a large culm. The stems are firm, jointed, and when dry are straw-like. They rise to a height of two feet or more from thick masses of short rhizomes, bearing numerous rootlets in company with several other stalks. When grown from seed it appears not to flower during the first year, but, sending up a few leaves, extracts from the earth enough nutriment, which is stored in the rhizomes, to permit of its full maturation during the following season. The culms are jointed, long, narrow-leaf blades springing from each node. The terminal part bears a bloom, with hermaphrodite spikelets, each one-flowered, and with two empty glumes. The flowering glumes are entire, hard, narrow, and furnished with a long, stout, persistent awn. The ends become in the course of time very hard in texture. It is often termed locally "sleepy grass," but has been identified, through the kindness of Professor Balfour, with *Stipa viridula*, whose properties, he also informs the writer, have not been thoroughly investigated, as far as can be judged from reference to the literature

available in this country or from the statements of experts.

Haeckel mentions that this *Stipa* exerts toxic effects on cattle, that *Stipa inebrians*, another American species, acts similarly, in addition to the *Stipa sibirica* of the Russian steppes. The results which follow the ingestion of *Stipa viridula* are so well illustrated by the term "inebrians" that the active principle present in them may probably be discovered to be the same. Another Russian variety (*Stipa capillata*) causes very great annoyance to shepherds, as the pointed, hairy callus of its glume can work its way without much trouble into the skins of sheep, and penetrating the epidermis, aided by the backward direction of the hairs which cover it, frequently reaches the vital organs of the animal, and may bring about a fatal result. *Stipa spartea*, or the "porcupine grass" of North America; *Stipa tenacis*, or the esparto grass of Spain; and *Stipa pennata* and *Stipa tirea* of Russia, are closely allied forms.

From the personal evidence tendered, the action of the grass on horses and cattle—it has no action as far as his information goes upon sheep—resembles that of a narcotic, along with stimulation of the respiratory and urinary center, disturbance of the cardiac mechanism, and the production of irritation in the urogenital tract. In increasing the flow of sweat it acts like opium. In about two days the more acute symptoms have passed off, but the general health of the animal suffers for some time. One of the inhabitants of the district was, at the writer's request, induced to eat some of the fresh grass, and experienced very much the same symptoms; here, however, his informant cannot enter into particulars.

The results which ensue upon the ingestion of *Stipa viridula* have nothing in common with the symptoms caused by the loco-weed. These are not due to any definite plant, but to organisms living on and swallowed with various kinds of fodder.

A weak solution of hydrochloric or acetic acid in water was found to be the most effective in the extraction of what presumably contains the active agent. Alcohol did not remove so much of the active body; its addition to the concentrated watery extract produced a copious precipitate, which was not inactive.

This paper simply purports to be a preliminary notice, and quantitative experiments have been found to be impracticable at pres-

ent owing to the difficulty hitherto found in separating some active body stable enough to resist drying and weighing even in the form of a salt. Injections of a liquid extract were not satisfactory; they certainly produced symptoms, but to what these symptoms were due it was impossible to say. Again, the acid extracts could not be used without at least partial neutralization, and this precipitated much of the solid material present.

If to an extract, made with dilute acetic acid by percolation for a day or two, carbonate of sodium or caustic soda was added, an almost white precipitate was produced, but a large excess of the alkali was required before the total precipitate obtainable appeared. The filtrate of this was yellow-brown in color, and if shaken up with ether, separated, and acidulated, and water added to the ether, minute quantities of a white amorphous body were obtained. The precipitate, washed on a filter-paper with dilute acetic acid, yielded, on adding carbonate of sodium to the filtrate, a precipitate of small white crystals or flocculi, soluble on heating, reappearing on cooling, soluble in acids, but precipitated partially by alcohol. The precipitate remaining dissolved in dilute hydrochloric acid, and only gave a small precipitate on adding an alkali, unless great excess was used, when a much denser yellow-white substance formed and fell. On evaporating any of the solution to dryness, when by evaporation of water the acid remaining became of great strength, decomposition occurred with the formation of colored bodies. Pure sulphuric acid added to the flocculi which fell on the addition of an alkali, after they had been purified and dried at a low temperature over sulphuric acid, gave a bright red violet color.

Alcoholic extracts were used at first, with a strength equal to two parts by weight of the grass in one of the extract. This extract was gently heated to drive off the alcohol, and then made up to its former strength with water. Analysis showed that it contained: Total solids, 9.88 per cent.; ash, 2.68 per cent.; organic solids, 7.20 per cent. Chlorides and sulphates were present.

*Experiment I.*—5.48 P.M. The frog, weighing 22 grammes, was injected with 6.53 cubic centimeters of the extract, or from 1.06 grammes of grass, equal to 24 cubic centimeters of the extract and 48.18 grammes of the grass per kilo.

5.46 P.M. A discharge of green feces from the bowel.

5.46½ P.M. Lying flat on back, motionless.

5.47 P.M. Able to move very sluggishly.

5.48 P.M. Respiration only 32 per minute, deep and full; one hind leg dragged.

5.55 P.M. If turned on back, is unable to regain normal position; breathing, 85 per minute, shallow; sits up with difficulty; cannot jump; hind legs weak.

5.58 P.M. All legs weak, but also in spastic condition.

6.10 A.M. Frog a little more lively; can turn half over from back, but legs stiffen on exertion; waddles, does not jump, bringing fore legs alternately high and straight out, and dragging hind legs; sits with hind legs curled up in front resting on fore legs.

Later. Gradually recovered from all the symptoms.

*Experiment II.*—12.5 P.M. A frog weighing 20.5 grammes was given an injection of the extract equal to 24 cubic centimeters per kilo, or 48 grammes of the original grass. The organic solids equaled 0.87 gramme per kilo.

12.40 P.M. Lying prone; irritation of feet caused movement of leg; no respiration or heart beat visible. Practically dead. Killed; the heart when placed in saline solution beat twenty-three times in the minute; the ventricular systole much prolonged, the auricles contracting more strongly. Two drops of the extract dropped upon the heart increased the vigor, but not the rate of its beat.

12.53 P.M. Heart stopped.

*Experiment III.*—Another frog, injected with 0.97 gramme per kilo, showed similar symptoms, but to a slighter degree, and recovered from the effects in some hours.

*Experiment IV.*—The very copious precipitate which fell on the addition of a moderate excess of carbonate of sodium was treated with dilute acetic acid after it had been caught on a filter-paper, and washed with a solution of the same salt. The acetic extract was made alkaline again with the carbonate, and thoroughly shaken up with ether in a separator. The watery portion of the mixture was removed after twenty-four hours, and a small quantity of a solution of hydrochloric acid in water added to the ether and shaken up with it. The acid watery solution was then removed from the ether. Carbonate of sodium added to alkalinity, and the resulting white precipitate washed by decantation with weak solutions of the salt.

Only a qualitative experiment was made as to the effect of this precipitate, which was

only slightly crystalline under the microscope, largely amorphous. Attempts to weigh the amount of the actual body present at 100° C. failed.

A large rabbit was injected at 12.50 with 25 minims of a suspension of this precipitate, which was so fine that no difficulty occurred in its injection.

12.50 P.M. Twenty-five minims injected under skin of back. Pupils widely dilated.

12.52 P.M. Legs paretic; shivering.

12.53 P.M. Both front legs lame.

12.54 P.M. Pupils contracted, breathing hurried, restless in aimless way.

12.57 P.M. Every now and then stopped moving, and seemed about to fall asleep.

1 P.M. Inclines to one side when moving, cannot hop, drags hind legs.

1.1 P.M. More restless again; movements when walking similar to crawling.

1.2 P.M. Pupils less contracted.

1.3 P.M. Heart beating 143 to minute; breathing rapid.

1.5 P.M. (fifteen minutes' interval). Same dose repeated. Pupils dilated at moment; contracted almost at once after the injection.

1.6 P.M. Appeared frightened from imaginary causes. Went backwards for some yards. Pupils almost pin-point, but changing very irregularly. Breathing 184 a minute.

1.10 P.M. On several occasions almost closed eyes; remained quiet; appeared to be nearly asleep. Movements crawling.

1.30 P.M. Has become brisker; still unable to move freely by hopping. When sitting head leans to one side and legs are spread out.

2 P.M. Lethargic, stupid, not so paretic, but less inclined for voluntary movements.

No urine or feces were passed. The rabbit lost all its previous plump, puffed-out look, its hair flattening down and becoming awry.

As far as these observations go little more can be advanced than that *Stipa viridula* contains some body or bodies which it is difficult to isolate, but which cause marked symptoms in frogs and rabbits as well as in the horses and cattle observed in its habitat. From the descriptions given based upon frequent personal observation, the grass appears to act not only as a powerful nervous narcotic, but as a diuretic, a sudorific, and as an irritant both of the respiratory and cardiac organs.

In the frog and rabbit a narcotic and paralytic power is well shown, but in the frog the respiratory movements appear to be slower, the heart acting in a manner somewhat recall-

ing digitalis; while in the rabbit the pupils are contracted, the respirations and heart-beat are quickened, while the behavior of the animal strongly suggests the idea that it suffers from hallucinations. The movements of fright shown by the rabbit, evidently arising from imaginary objects apparent in front of it, were most marked, and culminated in its retrogression backwards for some feet, a movement unsuited to the rabbit's conformation, and most unusual in the species, while alarm was indicated by the position of the ears and the constant shrinking back of the head.

Though *Stipa inebrians* and *Stipa viridula* may be different plants, the effects on the rabbit undoubtedly suggest that *Stipa viridula* was the cause of this cuniculus inebrians.

#### A PRELIMINARY NOTE ON THE PHARMACOLOGY OF THE ALKALOIDS DERIVED FROM THE MEXICAL PLANT.

Our readers may recall papers by Dr. Weir Mitchell and Dr. Prentiss on this subject. In the *British Medical Journal* of October 8, 1898, Dixon tells us that the plant *Anhalonium Lewinii* belongs to the small group of the Melocactææ, and is native to Mexico. It is used by the Kiowa and other Mexican Indians during certain religious ceremonies; they eat the so-called dried fruits, or, as they are termed by the natives, "mescal buttons." Lewin, Prentiss and Morgan, Weir Mitchell and other Americans, have made some few experiments by eating the buttons, but no account has at present been given of the pharmacology of the derived alkaloids. Heffter has described a method by means of which four alkaloids were prepared.

Mr. Edmund White, B.Sc., pharmacist at St. Thomas's Hospital, by a method modified from Heffter's, prepared for Dixon four crystalline alkaloids from the "mescal buttons;" the alkaloids and percentages obtained were as follows:

1. Mescaline	}	1.16 per cent.
2. Anhalonidine		
3. Anhalonnine		6.46 per cent.
4. Lophophorine		0.13 per cent.

All are freely soluble in water, and possess a remarkable similarity in their physiological actions. It is not proposed here to give detailed differences between these substances, but only to indicate the general conclusions obtained. The following data apply to all:

*Skin*.—Absolutely non-irritant, hence injec-

tion is a suitable mode of administering the alkaloid. A five-per-cent. solution has no effect when applied directly to the conjunctiva.

**Mouth.**—The substance behaves as a specific sialagogue.

**Gastro intestinal.**—After large doses nausea and vomiting may occur. Small doses are apt to cause constipation, but when the dose is large diarrhea sometimes occurs, and in exceptional cases even bloody stools have been observed.

These results are produced whether the alkaloid is given by injection or by the mouth.

**Blood.**—No effect.

**Circulation.**—From the therapeutic point of view this is the most important action, although any action on the circulatory system by this plant has been denied by some observers. Small doses slow the heart and cause it to beat much more vigorously, whilst after a varying period, dependent on the dose, the beat recovers its normal rate and generally exceeds it, but is never very rapid.

There is also a considerable rise in arterial pressure. These results are probably due (a) to direct stimulation of the intracardiac ganglia and nerve terminals of the vagus, and (b) to stimulation of the vasomotor center.

In toxic doses paralysis of the nerve endings of the vagus and subsequently of the nerve cells occurs. In a cat, after section of both vagi, the heart-beat was slow and arterial pressure increased by an injection of 0.025 gramme of the alkaloid, when a strong stimulation of the vagus failed to produce inhibition.

**Respiration.**—In moderate doses no effect. Toxic doses give rise to rapid shallow respiration, and death subsequently occurs from failure of the respiratory center. This is the main danger to be apprehended when experimenting with the drug in the human subject.

**Nervous.**—There is a preliminary stage of excitement, talkativeness, and exuberance of spirits, followed by a stage of intoxication. Like Indian hemp its effects vary considerably in different individuals. During the stage of intoxication there are increased reflexes, wide dilatation of pupils, auditory and nasal hyperesthesia, incoordination, tremors, blunting of cutaneous sensation, a rapid flow of ideas with difficulty in concentrating the attention, and sensory hallucinations, especially visual.

These latter consist of a kaleidoscopic play

of colors ever in motion and the tints constantly changing. The movements may be linear, rotatory, or pulsating. The visions generally are only seen with closed eyes. Coloring of external objects is exaggerated. Intellection and introspection seem to the experimenter to be normal. Occasionally there is an indescribable sensation of dual existence.

Lethal doses produce complete paralysis, and death is due to respiratory failure. Post mortem, a faradic current applied to the motor nerves produces contraction.

The important effects of these alkaloids in therapeutic doses would appear to be:

1. A direct stimulation of the intracardiac ganglia.
2. An initial slowing of the heart.
3. An elevation of arterial tension.
4. A direct stimulation of the brain and motor centers of the cord, as shown by the increase in reflex excitability.

#### TREATMENT OF POISONING BY MUSH-ROOMS.

In a recent issue of the *Philadelphia Medical Journal* PRENTISS thinks that a consideration of the symptoms and of the known physiologic action of muscarine (the mushroom poison) indicates the measures of treatment which are most efficacious.

Clear out of the stomach and bowels any of the fungi that may remain. As emetics, the non-depressing emetics, sulphate of zinc and sulphate of copper, are preferable. They are prompt and thorough in their action. But it may occur that emetics given by the stomach fail to act, on account of a benumbed condition of the nerves. Then apomorphine, four milligrammes hypodermically, and repeated, if necessary, should be tried. If these be not at hand use mustard, a tablespoonful in half a tumblerful of water, repeated if necessary. Sulphate of zinc 1 gramme (15 grains) every fifteen minutes until vomiting occurs. Sulphate of copper 0.30 gramme (5 grains), every fifteen minutes until vomiting, may serve. The importance of not leaving any of the mushrooms in the stomach or intestines appears from the fact that in autopsies in cases of mushroom poisoning portions of the fungi are found in the alimentary canal.

In consequence of this, there is progressive absorption of the poison going on from the inception until this debris is got rid of. No doubt many of the fatal cases so result from

this cause. Muscarine is rapidly eliminated by the kidneys, and if we can rely upon the reports concerning urine-drinking by the Kamchatkan debauchees it must be very completely eliminated.

If these agents fail, wash out the stomach with the stomach-pump. To act on the bowels, castor oil is preferable, to which, in cases of torpidity, croton oil may be added. Purgatives producing watery exudation into the intestines, such as the salines, should not be given, because water dissolves the muscarine and might thus promote its absorption.

Atropine is the physiologic antidote to muscarine. It should be given without delay hypodermically, in doses of from one-half to one milligramme ( $\frac{1}{16}$  to  $\frac{1}{8}$  grain), until it shows its characteristic action on the system, and then the effect kept up as the severity of the case may demand. Dilatation of the pupils, seen in some cases, is probably due to atropine.

Sustain the action of the heart. From heart failure comes the principal danger. First of all in importance is absolute rest in the recumbent posture; then, as in case of aconite poisoning, give the tincture of digitalis, ten drops every two or three hours, according to the effect. If there should be blanched skin, pale face, and cold extremities, give nitroglycerin, one milligramme ( $\frac{1}{8}$  grain) hypodermically, as frequently as required, instead of the digitalis. If the heart still continues weak and the vital powers are sinking, galvanism to the cardiac region and inhalations of oxygen may be employed. Efforts to keep the patient alive should be unrelenting, for we know that if the crisis can be tided over, Nature will eliminate the poison and recovery be assured. If death does not occur by the end of the third day, recovery is probable. Other unfavorable symptoms are to be appropriately met as they occur. For nourishment, concentrated foods are preferable, such as the meat extracts, egg albumen, milk, and the like. Nourishment is best given in small quantity at frequent intervals.

There is no chemical antidote to muscarine known. Tannic acid, the chemical antidote to alkaloids generally, does not precipitate it. Acidulated water (vinegar and water) used before cooking, to remove the poison from these mushrooms, would be worse than useless as an antidote. It dissolves the poison and would promote its more rapid absorption.

#### *DIRECT AND INDIRECT DAMAGE TO THE GENITAL TRACT.*

At the February meeting of the St. Petersburg Obstetrical Society, Dr. Barsoukoff read notes of a case of sloughing of the vagina. The patient had been admitted for poisoning by sulphuric acid. Eight days later the first reported sign of pelvic trouble set in, the surgeon noting slight vaginal hemorrhage, and four days afterwards he withdrew from the vaginal canal a cylindrical sloughy membrane. It included the whole mucosa and much of the submucous tissue of the entire upper third of the vagina. There was no rise of temperature through the whole course of the case. Very naturally it might be concluded that sulphuric acid had not only been taken by the mouth but likewise injected into the vagina. There was no reason, however, for such a supposition in this case. Clinical evidence was entirely against it, as there was no trouble in the pelvic region till over a week after the poisoning. On the other hand, it is quite reasonable to assume that the sloughing of the vagina was due to the sulphuric acid poisoning. One effect of the acid when taken by the mouth is acute irritation of the alimentary canal. Now, as Harley, Hutchinson, and others showed many years ago, enteritis may be followed by discharge of the vaginal mucous membrane.

Dr. Rhys Griffiths, of Cardiff, contributed to our columns a valuable paper on this subject. His own case deserves study, as, unlike that above related, which was extremely acute, the affection lasted for years, shreds of vaginal tissue coming away from the vagina from three to four inches long and from one to two inches wide. The abdomen was often swollen, and there was intestinal irritation. What was much more comprehensible, as the latter complication was evident, was the passage of shreds from the rectum. The primary disease was in fact mucous colitis or membranous enteritis, more frequent in women than in men. Barsoukoff related three more cases in his own experience, all in typhoid fever patients and all at the beginning of the fourth week. In all the vaginal mucous membrane came away more or less complete as a slough, just as in his first case, which was clinically even more acute. At the annual meeting of the Obstetrical Society of London in February, 1896, Dr. Playfair exhibited a slough forming a complete cast of the vagina from a case of typhoid. In chronic cases like that of Dr. Rhys Griffiths the vaginal mucosa comes

away in shreds. In short, for reasons on which pathologists are not agreed, enteritis may cause membranous vaginitis, whilst if the primary intestinal lesion be acute the vaginal mucosa may come away as an actual slough.

This remarkable symptom, then, must not be taken as proof of local violence or of the felonious administration of local applications. On the other hand, improper local applications may cause complete mucous casts of the vagina to come away quite painlessly. Mr. Targett exhibited a very perfect cast at the July meeting of the Obstetrical Society in 1895. The patient was a very neurotic single woman, aged thirty-five. She had been told by an eminent authority that she had nothing the matter with her. Acting afterwards on the advice of a friend she began a course of local treatment by a quack remedy. A medicament in the form of a cylinder was slipped into the vagina, and after an interval of from three to five days the cast was shed after vaginal injection. Another cylinder was then introduced and the process repeated. Within ten months no fewer than fifty casts were expelled, and the patient seemed none the worse. As in Barsoukoff's typhoid cases, stricture of the vagina does not seem to follow these exfoliations.

The medical jurist may learn from these cases that the vaginal mucous membrane is very prone to come away in certain circumstances. The phenomenon is not, however, produced by ordinary local violence, but from different causes, one being quite the opposite to local.—*British Medical Journal*, July 16, 1898.

#### TREATMENT OF PULMONARY TUBERCULOSIS.

To a recent number of *La Médecine Moderne* MIGNON contributes his views. He says that he finds that almost all of the evil symptoms of pulmonary tuberculosis can be largely modified by immobilization of the thorax, in much the same way as one would treat a case of early pleurisy. Thus he finds that thoracic pain and neuralgic attacks, the cough, the vomiting, the tendency to hemoptysis and even the expectoration are decreased by this means, and more surprising than all, that the temperature is somewhat controlled. We should think that this treatment would possess advantage in direct proportion to the painfulness of the case, and

that where the lung was already much involved, so that it was difficult for the patient to breathe, the fixation of the chest would be practically unbearable to the patient.

#### THE USE OF SUPRARENAL GLAND IN THE TREATMENT OF CHLOROFORM ACCIDENTS.

In the *Revue de Thérapeutique Médico-Chirurgicale* we are told that MINKOWSKY has repeated the experiments of Biede and of Gottlieb and has found that the use of suprarenal gland in the lower animals does much towards preventing accidents during the administration of chloroform, probably through its powerful influence on the vascular system.

#### THE TREATMENT OF CHRONIC COLITIS IN CHILDREN.

*La Presse Médicale* in a recent issue contains a paper by ROMME upon this topic. After pointing out that the therapeutic indication in most of these cases is multiple, he also points out that hydrotherapy in the form of frequent and prolonged baths, sometimes hot and sometimes cold, according to the reaction of the child, is useful; that it is absolutely essential to regulate the diet; and that in many cases the administration of broths, vegetable or animal, is extremely useful in place of milk. Where it is evident that there is deficient gastric digestion care must be taken that all meats are carefully pulped or minutely subdivided before they are swallowed. Well-toasted bread should be used, and the following formula may be prescribed:

- ℞ Hydrochloric acid, 5 drops;
- Distilled water, 3 ounces;
- Gum arabic syrup, 6 drachms;
- Tincture of opium, 2 drops.

One to two teaspoonfuls twice a day.

Should there be evidently much inflammation of the large intestine, hot baths every two or three days, with hot compresses applied night and morning over the abdomen, are very useful; and lavage of the intestine with hot water which has been boiled, and to which has been added borax in the proportion of 2:1000, or the decoction of chamomile, exercises a useful influence upon the mucous membrane. The compresses and the baths relieve pain. Sometimes minute flying blisters applied to the abdomen are of value. Where it is evident that putrefaction is going on in the intestine and the colitis is chronic

so that the stools are very evil in odor, it is well first to give minute doses of calomel in the following prescription until the mucus is thoroughly removed from the bowel:

- ℞ Benzo-naphthol,  
Beta-naphthol, of each 2 grains;  
Salicylate of bismuth, 1 grain;  
Powdered sugar, or powdered gum arabic, 5 grains.

Make into one powder and give three of these powders a day to a child of four years.

This treatment should be continued for four or five days. Should the pain be very severe minute doses of opium may be given. Antipyrin is not satisfactory, as it does not thoroughly relieve the pain and is apt to diminish the secretion of urine, but should the fever be marked and it be impossible to reduce it by cold, then antipyrin may be used. Should evidences of collapse come on in the treatment of enterocolitis of children, copious intestinal irrigation with normal salt solution is to be resorted to to wash out the putrid material and to supply the body with liquid. In some instances the large bowel will be soothed by the injection of considerable quantities of olive oil, the soft-rubber tube being pushed high in the bowel and three or four ounces of oil given.

#### FORMULA FOR THE TREATMENT OF GOUT.

The following formula is stated by the *Klinische Therapeutische Wochenschrift* to be useful in the treatment of gout:

- ℞ Sulphate of quinine, 1 drachm;  
Citric acid, 2 drachms;  
Simple syrup and syrup of orange flowers, of each 2 drachms;  
Distilled water, 6 drachms.

Ten drops of this mixture in an ounce of water, to which is added twenty grains of bicarbonate of sodium, will it is stated make a pleasant effervescent quinine draught.—*La Médecine Moderne*, July 13, 1898.

#### THE TREATMENT OF POST-PARTUM ECLAMPSIA.

The *Journal de Médecine de Paris* of September 25, 1898, outlines the following treatment: In many cases bleeding is the best remedy to which we can resort. As much as ten to sixteen ounces is to be removed. If insomnia and nervous irritation persist a full dose of chloral may be given by rectal injection, as for example as much as one drachm in three ounces of milk, and if quiet is not obtained by this injection it may be repeated

three times until as much as two to three drachms of chloral has been given in twenty-four hours. With other persons purgative treatment designed to eliminate the poison is resorted to, or in other instances diuretics are employed. The best diuretic under these circumstances is to inject beneath the skin artificial salt solution in the dose of about one pint per day. This is particularly useful with the bleeding. Still another method is to employ large and complete irrigation of the large intestine, two to three quarts of boiled water as hot as can be readily borne being passed into the bowel and kept circulating for a period of thirty to forty minutes, and being repeated two or three times in a period of twenty-four hours.

#### THE USE OF THE SULPHATE OF SODIUM IN CATARRH OF THE STOMACH.

SIMON, of Vienna, uses small doses of sulphate of sodium for the treatment of this condition. He usually gives from ten to fifteen grains of it in about six ounces of hot water, and under these circumstances the catarrhal condition of the stomach, with its hyperacidity, passes away and the sensations of pain and discomfort in the epigastrium with nausea are relieved. This method of treatment is supposed to do good by improving the motor power of the stomach.—*La Médecine Moderne*.

#### THE INFLUENCE OF MORPHINE AND ETHER UPON THE CONTRACTIONS OF THE UTERUS AND ABDOMINAL PRESSURE.

HENSSEN has studied the action of morphine and ether in twelve parturient females, the greater number of whom were primiparæ. The morphine was administered subcutaneously in the dose of  $\frac{1}{10}$  to  $\frac{1}{4}$  of a grain, and the ether was given by inhalation up to the point of producing profound sleep. His conclusions are that morphine given in the dose we have named does not exercise any material influence upon the action of the uterus nor upon abdominal pressure; that inhalations of ether for the first one or two minutes cause a notable diminution in the energy of the uterine contractions and in their frequency. The action of the uterus returns to normal five to twenty minutes after the cessation of the inhalations, and finally the abdominal pressure is completely removed during the time that the ether sleep is in existence.—*La Presse Médicale*, September, 1898.

*THE TREATMENT OF DIABETIC COMA  
BY THE BICARBONATE OF  
SODIUM.*

The *Revue de Thérapeutique Médico-Chirurgicale* of September 1, 1898, tells us that Besson has recorded a case in which diabetic coma was markedly influenced for the better by hypodermoclysis, using six drachms of bicarbonate of sodium and two drachms of chloride of sodium in each liter of water. He concludes that this method of treatment offers us incontestable good results in the treatment of diabetic coma. Sometimes intravenous injections may be advisable. It is well in some cases to interfere before the coma develops.

*THE TREATMENT OF DIPHTHERITIC  
PARALYSIS.*

PLICQUE writes on this topic in *La Presse Médicale* of August 25, 1898, and while it is to be remembered that the prognosis in many cases of diphtheritic paralysis is favorable, what he has to say in regard to its treatment is interesting. After calling attention to the absolute dietetic needs of the patient and the fact that though food is always required it is sometimes difficult for the patient to swallow it, he recommends that it should be given in small quantities frequently and in such a form as to be readily digested and assimilated, and that in pressing cases gavage shall be resorted to where swallowing is so difficult that insufficient quantities of food can be taken. Where vomiting is present after each meal, then small quantities of champagne or shaved ice must be used. Sometimes the disorder of the stomach depends upon partial paralysis of the bowel, with consequent constipation. In other instances where the stomach is alone at fault, alimentation by the rectum, the subcutaneous injection of artificial serum and similar supportant measures must be employed. Sometimes, too, the application of the positive pole of the battery to the nape of the neck, the negative small pole being placed over the stomach, and eight to ten milliamperes of electricity used, will be of value in stopping the vomiting.

Among the nervous tonics which the author thinks are inoffensive he mentions kola, cocoa, the glycerophosphates, phosphide of arsenic, and strychnine. Phosphide of arsenic he thinks is useful in gastro-intestinal cases, and the strychnine particularly useful in those cases where there is muscular failure. Under these circumstances it may be

given hypodermically directly into the part which is affected.

In the way of local stimulant applications the writer advises salt baths, stimulating irrigations, massage, and similar measures. Sometimes electricity may be used with advantage. Where there is paralysis of the palate he applies the small pole of the battery to the neighborhood of the stylo-mastoid muscle, with the other pole in the posterior portion of the mouth or under the angle of the jaw, a feeble current being used and the séance lasting about ten minutes. The applications of this character which are made inside the mouth are exceedingly disagreeable to the patient and ought not to be attempted except in obstinate cases. The positive pole is placed upon the nape of the neck in other instances, and the negative pole armed with a small piece of moist cotton is applied to the neighborhood of the palate. Three milliamperes is quite sufficient. In paralysis of other muscles a pole may be applied to the nape of the neck, and the negative pole made in the form of a roller is then passed over the muscles which are paralyzed, the séance lasting about ten minutes. Plicque even asserts that application of electricity may prove useful in feeble vision.

*THE TREATMENT OF SORE MOUTH IN  
PREGNANT WOMEN.*

For the prevention of this complication of pregnancy *La Presse Médicale* of September 21, 1898, recommends the habitual use for four months prior to parturition of a mouth-wash designed to prevent acid formations in the mouth. The patient should visit a dentist in order to have the teeth thoroughly cleansed and carious places attended to. In many instances it is necessary to restore or maintain the normal alkalinity of the buccal secretion by alkalies such as the bicarbonate of sodium. The following may be used as a mouth-wash or dentifrice:

- ℞ Bicarbonate of sodium,  
Carbonate of lime, of each 10 drachms;  
Refined camphor, 2 drachms.

Or,

- ℞ Carbonate of lime, 10 drachms;  
Salol, 2 drachms.

In rebellious cases where there is much swelling of the gums and mouth a wash of chlorate of potassium may be necessary, or it may even be necessary to touch the ulcerated spots with permanganate of potassium. The following formula may prove useful:

- ℞ Chlorate of potassium, 1 drachm;  
Rose honey, 2 drachms;  
Glycerin, 6 drachms.

In very obstinate forms the spots may be touched with the following mixture:

- ℞ Tincture of iodine, 2 drachms;  
Glycerin, 6 drachms.

When permanganate of potassium is used, we employ permanganate of potassium 3 grains, distilled water 1 ounce.

#### THE ANTITOXIN PATENT.

We would not be behind our contemporaries in condemning the recent action of Professor Behring in applying for a United States patent for diphtheria antitoxin. If there is an axiom of medical ethics more binding than others, it is that no device which promises important aid to the health and well-being of the State should yield profit solely to its discoverer. Free trade in valuable discoveries has hitherto been maintained by the profession as trustees of the public health; now we have to face the misfortune that a man of eminent skill has not only claimed, but has succeeded in obtaining, a patent for that which is not solely his own. To all such attainments as that of the diphtheritic antitoxin the work of many men contributes; and in morals there can be found no sanction for this deplorable procedure.—*Quarterly Medical Journal*, October, 1898.

#### THE TREATMENT OF PRURITUS.

The *Revue de Thérapeutique Médico-Chirurgicale* of September 15, 1898, contains an article by LAVALLEE upon this topic. After discussing the various causes of pruritus he speaks of the internal treatment and suggests the use of antinervines, such as valerian, the bromides, and asafetida, the tincture of belladonna and the tincture of aconite, and sometimes the use of the tincture of gelsemium. Of the other remedies which have been administered internally in pruritus he mentions hamamelis, digitalis, ergotin, and even quinine and pilocarpine. Opium and chloral are not to be forgotten in severe cases. The external treatment consists in the use of baths at home or at natural springs, particularly the use of those waters which are mildly alkaline, and the application of cold douches or very hot douches prolonged through a sufficient period and making distinct influence upon the peripheral nervous system. In other instances a wash of dilute alcohol

or vinegar or the application of hot compresses to the itching part will be of value, the hot compress being covered with rubber dam to maintain heat and moisture. In senile pruritus the following prescription may be used:

- ℞ Bromide of potassium, 2 drachms;  
Iodide of sodium, 1 drachm;  
Salicylate of sodium, 2 drachms;  
Acetate of sodium, 1 drachm;  
Infusion of gentian, 4 ounces.

Two teaspoonfuls in water after each meal.

At night hot lotions may be applied to the body in the form of a 1:2000 solution of corrosive sublimate, carbolic acid in the strength of 1:20, or the salicylate of bismuth with ten to twenty per cent. of powdered starch; or the following ointments may be advised:

- ℞ Menthol, 5 grains;  
Guaiacol, 1½ drachms;  
Salicylic acid, 30 grains;  
Lanolin, 1 ounce.

Or,

- ℞ Carbolic acid, 1 drachm;  
Hyposulphite of sodium, 1 ounce;  
Glycerin, ¼ ounce;  
Distilled water, 10 ounces.

Or,

- ℞ Vinegar water, 1 drachm;  
Ichthyol, 1 drachm;  
Glycerin (with or without menthol), 1 drachm.

In some cases a two-per-cent. solution of permanganate of potassium is useful, followed by an application of oxide of zinc. Where the pruritus is limited to a small area we may use menthol 30 grains, alcohol 6 drachms, and ether 6 drachms, or menthol may be used in chloroform to the point of saturation. In other cases we may give:

- ℞ Cherry-laurel water, 2 ounces;  
Chamomile water, 1 ounce;  
Alcohol, 1 ounce;  
Chloroform, 5 drops;  
Corrosive sublimate, 3 to 4 grains.

Or,

- ℞ Cocaine hydrochlorate, 45 grains;  
Chloral, 1 drachm;  
Cherry-laurel water, 2 drachms;  
Distilled water, 1 pint.

For pruritus of the anus laxatives may be used or rectal injections of very hot or very cold water may be employed, and just before retiring a one-per-cent. chrysarobin suppository may be introduced into the bowel. In other cases relief is obtained by making a local application of nitrate of silver, in the strength of 1 to 20, every three days.

For the treatment of pruritus of the scrotum a very hot solution of corrosive subli-

mate, or carbolic acid, may be applied on a compress and this enveloped in rubber dam. For pruritus of the vulva the following may be used:

- ℞ Hydrate of chloral, 1 drachm;  
Rose water, 3 ounces;  
Distilled water, 4 ounces.

Or,

- ℞ Morphine hydrochlorate, 6 grains;  
Cherry-laurel water, 1 drachm;  
Borate of sodium, 2 drachms;  
Chloroform water, 1 pint.

Or the following ointment may be used:

- ℞ Bromide of potassium, 30 grains;  
Salicylic acid, 7 grains;  
Calomel, 7 grains;  
Glycerole starch, 6 drachms.

Before retiring for the night it is well to apply and maintain in contact with the vulva hot poultices of linseed which has been moistened with boric acid water. In other cases a strong solution of nitrate of silver is to be applied:

- ℞ Nitrate of silver, 15 grains;  
Distilled water, 2 drachms.

Internally in pruritus vulvæ, if it be associated with a neurosis, sleep is to be obtained by a mixture of bromide of ammonium, chloral, and syrup of orange flowers, or by the use of sulphonal and antipyrin. Injections of lysol and corrosive sublimate are also of value to prevent vaginal discharges from irritating the vulva. Pruritus of the palm of the hand is to be relieved by remedies similar to that applied to the scrotum.

#### DIABETIC COMA AND ITS TREATMENT.

The *Bulletin Général de Théraputique* of September 15, 1898, contains an exhaustive article on this subject by ROBIN. After discussing the various forms of diabetic coma he indorses the recommendation of Lepine that the following intravenous injection should be used in these cases, namely:

- ℞ Chloride of sodium, 1 drachm;  
Bicarbonate of sodium, 2½ drachms;  
Distilled water, 1 quart.

In addition we should institute at once in place of the antidiabetic diet a strict milk diet, and we should aid the elimination of poisons by the intestine by the administration of saline purgatives, of which probably sulphate of sodium is most efficacious. We may also give full doses by the mouth, amounting to six drachms of the bicarbonate of sodium, to saturate the acids of the body; and should the heart be feeble or

irregular we should administer full doses of digitalis and ergotin. The main indications for treatment under these circumstances are to maintain the action of the nervous system, to aid in the elimination of poisons by the kidneys, intestines, lungs, and skin, to render alkaline the liquids of the body and destroy toxins, to maintain the force of the heart, and to relieve gastro-intestinal fermentation.

#### SUBCUTANEOUS INJECTIONS OF MEDICATED OILS.

In *La Presse Médicale* of September 7, 1898, LETULLE states that he has obtained excellent results in certain cases of visceral tuberculosis by the injection of large quantities of olive oil into the subcutaneous tissue. He regards as absolutely essential to the success of this treatment that it shall be done sufficiently slowly and that absolute asepsis shall be maintained. Guaiacolated olive oil of the strength of one grain of guaiacol to 1000 cubic centimeters of oil is used, after having been sterilized by heat, and is then placed in a wash-bottle which has been sterilized. This wash-bottle is arranged exactly in the same manner as an ordinary atomizer, with a hand-ball air pump attached to the tube running into the surface of the fluid, and a trocar attached to a rubber tube leading off from the inside tube which is sunk deeply into the oil. By this means the oil is forced out into the subcutaneous tissues, and to prevent the air from carrying micro organisms into the oil it is filtered in its course through the tube by passing through some sterilized cotton, which is placed in the dilated portion of the canal. Under these circumstances quantities as large as from two to four ounces of guaiacolated oil may be given beneath the skin and repeated every two days. By using the injection very slowly pain is avoided, and the oil, he states, is readily absorbed.

#### MOVABLE KIDNEY AND ITS TREATMENT.

In an interesting paper on this subject in the *Medical Record*, EINHORN asks the question: Shall the treatment of movable kidney be surgical, or are medical therapeutic measures sufficient? The statements made in the literature regarding this point are widely divergent. On the surgical side, this operation is regarded by some as the only curative measure. Thus, for instance, Edebohls says

that the symptoms of movable kidney may be improved by the dorsal posture, the Weir Mitchell treatment, massage, electricity, and abdominal bandages; all these measures, however, fail in the vast majority of cases, and even the improvement obtained is usually only of transient character. A nephrorrhaphy properly performed in appropriate cases, as demonstrated by his own experience, always brings about improvement and presents a good prospect of a permanent cure. Lewis, who has recently written on this subject, also contends vigorously in favor of operative treatment. On the other hand, Landau is opposed to all surgical intervention, and Huber remarks as follows: "In reference to the therapeutics of enteroptosis, I would emphasize that, up to the present time, I have never been induced, owing to the severity of the symptoms or inefficacy of the adopted non-operative treatment, to refer the patients to the surgeon for the performance of nephrorrhaphy, the most radical treatment which at present still appears admissible. This much can be said, at any rate: that an intelligent application of bandages, in connection with an appropriate dietary and medicinal treatment of the gastric symptoms, will, as a rule, be adequate." Boas also does not appear to be a vigorous supporter of surgical procedures.

The author's own experiences point decidedly in favor of medical treatment, and for the following reasons:

The results of internal dietetic-mechanical treatment are very favorable, if the gastric and intestinal symptoms are treated according to modern methods, if attention is paid to promoting nutrition, and, if necessary, the wearing of an appropriate abdominal bandage is recommended. On reviewing once more the cases of digestive disturbances in connection with floating kidney treated with electricity (electrization was employed on account of the severe gastric symptoms, and not on account of the condition of the kidney), the writer finds that among the above mentioned forty-three patients, twenty-seven were completely cured—that is, all the subjective symptoms disappeared—and sixteen were considerably improved. The results were equally favorable in many cases in which electricity was not applied. He refers only to the above cases, however, because he possesses accurate data regarding them, and had them for a great length of time under observation.

As is generally known, very many cases of

movable kidney are unaccompanied by symptoms. We find a large percentage of digestive disturbances in patients affected with floating kidney, because these ailments afford us the opportunity of examining the patient. If we were to examine all healthy persons; it would soon come to pass that digestive disturbance in subjects of floating kidney perhaps do not occur much more frequently than in those whose kidneys are in a normal position.

These digestive disturbances in the vast majority of cases, therefore, do not depend upon the movable kidney, but upon other general causes; hence an operation upon the kidney would not in the least remove the trouble. Moreover, movable kidney, as already mentioned above, is only one of the manifestations of a general enteroptosis, and suture of the kidney would not remove the ptosis of the other organs.

The results of nephrorrhaphy are in no respect better than those of rational medical treatment. As stated above, according to the statistics of Sulzer, the results were unsatisfactory in about one-third of the cases subjected to operative measures; aside from this, there are the risks of the operation, which still has a mortality of two per cent.

In the last few years the writer has personally had an opportunity of observing three cases in which nephrorrhaphy had been performed by well known New York surgeons, and in which no improvement whatever occurred after the operation. One of the patients, indeed, both of whose kidneys had been sutured, asserted that her ailment had become considerably worse since the operation.

That some surgeons are too quick to undertake the operation is shown by the following case, observed by the writer:

Miss L. N., twenty-four years old, came under observation May 12, 1898. For three years she had suffered from pains in the region of the stomach, which were especially intense about one hour after eating. The appetite was good, but, owing to dread of pain, the patient eats at present but little, and only the lightest food. Bowels are regular and urine is normal. The patient reported that about six weeks ago she had consulted a distinguished surgeon of New York on account of her ailment. This gentleman found a floating kidney on the right side, and explained to her that an operation was necessary. A nephrorrhaphy was then performed, but when, after three weeks' stay

in bed, the patient got up, her old disturbances returned with the same severity as formerly. Examination of the thoracic organs showed nothing abnormal. On examination of the abdomen, however, it was found that the greater curvature of the stomach was situated one or two fingers' breadth beneath the umbilicus. At no place was there any particular tenderness to pressure present. In the right posterior upper lumbar region a scar left after the nephrorrhaphy was observed. On May 14, 1898, an examination of the stomach contents one hour after the test breakfast showed: HCl +; acidity = 78; free HCl = 48. On May 16 the stomach was examined in the fasting state, and was found empty. A diagnosis of hyperchlorhydria was made, and the patient was directed to take frequent meals and alkalies. Since then she has felt better, although her pains have not been entirely removed.

While in general Einhorn is opposed to operative treatment in cases of floating kidney, he believes that in rare instances nephrorrhaphy may be justifiable, especially when a connection between the symptoms (both the direct as well as the gastro-intestinal disturbances) and a movable kidney appears to be proven in a high degree, and the above described dietetic-mechanical methods of treatment have completely failed. At any rate, every surgeon, before advising operative intervention in movable kidney, should completely exhaust the suggestions and remedies of the physician. By proceeding in this manner the vast majority of patients suffering from floating kidney will be relieved of their disturbances without any surgical intervention.

---

*THE RESULTS OBTAINED BY THE OPERATION OF PARTIAL THYROIDECTOMY IN EIGHT CASES OF GRAVES' DISEASE.*

In a recent issue of the *Medical Record* BOOTH writes on this topic, and after detailing cases and discussing the subject in general he thinks that it will be seen that the operation cured five of the eight patients. One died; in one no change has occurred; one has been improved, and in this case it is worthy of notice that the operation was performed only six months ago, so that we may expect still further improvement and perhaps a cure; for the longer the period of observation after operation the better appear

the results. The order of improvement in his cases corresponds with that observed by others: first the goitre diminishes, next the nervous symptoms disappear, then the pulse-rate and vasomotor phenomena improve, and the exophthalmus last of all.

Surgical intervention in Graves' disease has been espoused in the works of Stierling, Heidenreich, Lemke, Kocher, Buschan, Solary, and others, all reporting successful results in a number of cases. Solary in sixty-nine observations reports eighty-four per cent. improved. Heidenreich in sixty-one cases had fifty cures and five failures. Buschan gives the following statistics: 80 cases—31 cured, 20 improved, 6 deaths, 16 failures, 7 unknown results. Mikulicz in eleven cases had seven patients fully cured, and four essentially improved. Besides these, numerous other authors report cases cured or improved by operative measures.

The following is a list of fatal cases after partial thyroidectomy from 1890 to May 1, 1898: 1892, Lemke, 1; 1893, Cohen, 1; 1893, Wolff, 1; 1896, Mattieson, 2; 1896, Riedel, 5; 1897, Embden, 1; 1897, Lejard, 1; 1897, Wiesinger, 1; making 13 in all for this period. The deaths take place suddenly, either at the time of the operation or soon afterward, and the rapid onset of the acute symptoms, with death following in a few hours, has given rise to much speculation as to their cause.

Cases of Graves' disease may be entirely cured by operative measures. Pathological and clinical evidence is in support of the view that the symptom-complex is the expression of a primary neurosis multiplied by a secondary glandular intoxication. While the ultimate cause of the disease of the gland is still a matter of speculation, and a mortality of seven per cent. after operation is reported, we cannot justly recommend it as a routine plan of treatment. Sudden death may occur in the course of or soon after operation, and has not as yet received a satisfactory explanation.

---

*ACETATE OF THALLIUM FOR NIGHT SWEATS.*

COMBEMALE has recommended the acetate of thallium, which appears in a white powder readily deliquescent and soluble in water and in alcohol, in the dose of two to four grains a day in pill form for night sweats. He claims to have obtained excellent results. —*La Presse Médicale*, September, 1898.

*THE CHEMISTRY OF DIABETIC FOODS.*

It may be accepted as a truth, although some may dispute it and great commercial interests are opposed to it, that natural food simply cooked is the best for the sick as well as for the healthy, and that of the various artificial dietetic specialties, produced with so much ingenuity and supplied at so high a price, few are worth a tenth part of the money they cost.

In the treatment of diabetes the truth of this observation is being realized by many of those who have most experience in the matter, and attention is being directed at the present time rather to the inquiry how far natural articles of food may be permitted than as formerly to the invention of unpalatable, indigestible, and innutritious substitutes.

The modern physician is content to confine his absolute prohibition to cane and grape sugars, and articles of food which contain these substances, but he recognizes the desirability of permitting other carbohydrates, although only in quantities proportional to the assimilative powers of each patient. Chemical analysis has shown that many of the articles ordinarily excluded from a diabetic diet contain only small amounts of starch, or the less harmful forms of sugar, such as levulose; while it has also been demonstrated that most of the so-called diabetic foods contain a considerable, and some a very high, percentage of starch or sugar-forming carbohydrates.

For example, it is very usual to meet with patients who have been ordered to eat animal food, green vegetables, and gluten bread, no limit being attached to the last, although many kinds in the market contain quantities of starch varying in amount from thirty to forty per cent., and yet potatoes contain only fifteen per cent., and Jerusalem artichokes sixteen per cent. Fruit, which is so valuable an addition to a diabetic dietary, is usually totally excluded, although apples and sour oranges contain not more than about ten per cent. of carbohydrate, while rhubarb, green gooseberries, cranberries, bilberries, and currants range under four per cent. In a recent paper by Dr. F. Kraus, Jun., of Carlsbad, he has shown that cooking still further deprives many fruits and vegetables of their carbohydrate components. A raw apple containing 11.7 per cent. of carbohydrate after once stewing contained 7.3 per cent.; after twice, 6.1 per cent.; peaches contained 9.5 per cent. before cooking, and 1.8

per cent. after. He recommends that the water in which the fruit is stewed should be thrown away and a little flavoring added, such as cinnamon, cloves, or vanilla, as well as saccharine. In this way really palatable preserves are made in Germany for the use of diabetics, containing very little carbohydrate.

Vegetables may be made to take up a large amount of fat so as to form a very valuable addition to the diet, without becoming disagreeably greasy, as in salad (oil), or puree (butter), or by frying them in oil or fat. Dr. Kraus illustrates the futility of trusting to the general run of commercial articles sold as diabetic bread by a table showing the carbohydrate contents of most of those used in Germany. Of the nineteen specimens enumerated only five contain less than 30 per cent. of carbohydrate, four are between 30 and 40 per cent., four between 40 and 50 per cent., two between 50 and 60 per cent., and four over 60 per cent., as against ordinary white wheaten bread, which contains 60 per cent. He quotes a case mentioned by Professor von Noorden, which was sent to him as a severe case of diabetes, because on the strictest diet the sugar had gone up. This "strictest diet" consisted of meat soup, coffee, tea, eggs, meat, green vegetables, bacon, butter, and "conglutin bread," of which last 300 grammes was taken daily. This conglutin bread contained 38 per cent. of starch, and was equal to 200 grammes of white bread. On proper diet the sugar disappeared in two days, and the case proved to be really a mild one.

We could produce parallel examples of English diabetic bread and flour in every respect as bad as those made in Germany. It is not uncommon in England to meet with patients who are on what they believe to be strict diet; if they are asked whether they eat bread they promptly answer, "No, only toast," of which they take as much as they please. It is extraordinary that any virtue can be supposed to exist in toast, but it is a not uncommon delusion, as all consultants must be aware. Only a few weeks ago a letter was sent to the *British Medical Journal* by a correspondent who wished to impart his experience of what he called "strict diabetic diet" of this kind. Toast is useful for diabetics who can assimilate bread in any form, because it can be weighed accurately, and because it is less tempting to the appetite than fresh bread, but, unless it is burnt to carbon, it must contain as much carbohydrate.

Milk contains only four or five per cent. of milk sugar, and in limited quantities of half a pint to half a liter can generally be taken with safety; but a diabetic milk may be made by previously diluting the milk and then passing it through a separator so as to get nearly all the fat, and half or less than half of the other solids, in one portion. It can then be sterilized and sold in bottles. It would diminish the objection felt by many to this very valuable article of diet if such diabetic milk were prepared for sale in this country.

To sum up the lesson we desire to teach: (1) It is much better to allow a definite quantity—for example, two to four ounces of potato or toast—than to allow an unlimited amount of “diabetic bread” of unknown composition; (2) in many cases such definite quantities of natural foods are safer than even limited amounts of the less palatable and more expensive specially prepared articles; (3) when it is desired to place a patient upon strict diet, care should be exercised to see that he obtains his bread substitutes from a really trustworthy maker; (4) lastly, many fruits, especially if well cooked, may be added to the diabetic dietary. — *British Medical Journal*.

#### THE AMBULATORY TREATMENT OF FRACTURES.

During the past few years much has been written concerning the ambulatory treatment of fractures of the long bones. A great deal of interest has been manifested, both here and abroad, and a great deal of confusion—more than is warranted—seems to exist in the minds of some who have spoken and written upon the subject as to exactly what ambulatory treatment is. Many of those who have discussed the question appear to be under the impression that the ambulatory treatment of fractures consists in the application of a plaster-of-Paris splint, say to a fractured tibia, in the usual way, and the allowing of the patient to get about on crutches as well as he may be able to do. This method of treatment certainly cannot be designated as ambulatory, in the sense in which the term should be used. The patient is undoubtedly getting about, but it is largely his determination or his necessity and his success in learning to use crutches that enable him to do so. In these instances the discomfort of the patient is apt to be much increased by the swelling of his foot, which results in part from its dependent position

and in part also from the fact that the muscles are not acting, and accordingly are not assisting venous return.

Those writers and speakers who have the clearest conception of what ambulatory treatment really is have given us quite another picture. Still taking a fracture of the tibia with or without a fracture of the fibula as an example, we have described to us a radically different but superficially similar procedure. This true ambulatory treatment consists in applying the plaster of Paris to the limb so that it is suspended in a rigid case from the knee down, and is enveloped in soft material with a thick pad under the foot. The weight of the body in attempts at walking is carried by the splint, which must have a thickly padded collar of plaster of Paris at its upper end, just below the tuberosities of the tibia, upon which the weight of the body rests. The whole splint must be strong enough not to “buckle” under pressure, and still must not be so heavy as to prevent the patient getting about with ease. If we apply such an apparatus soon after the occurrence of the fracture, and allow the patient to attempt to walk, perhaps with the aid of one or two canes at first, we are really employing ambulatory treatment. The success of the method will of course depend to some extent upon the nature of the fracture, and we shall also find that patients will vary very much in their inclination to avail themselves of the possibilities of this method.

Fractures close to the knee-joint, especially if there is any comminution, would be better treated by some other method. Fractures of the femur may in some cases be treated by the ambulatory method, but the apparatus must necessarily be much more cumbersome, and the difficulty in maintaining sufficient extension may be considerable.

There is another side to the question in introducing a therapeutic measure which seems so different from accepted methods. Many surgeons would hesitate, and very justly, to attempt this form of treatment, because of its effect on the mind of the patient. The idea that a broken bone must be “set” and held firmly in position is so well fixed in the minds of the laity that, if we should neglect to go through some process which we must describe as “setting” with subsequent fixation, we may leave a germ in the patient's mind, the mature fruit of which will be a charge of incompetence and neglect, and a suit for malpractice in case the result should not be perfect, something which can

practically not be absolutely guaranteed. Wrapped up in this idea of "setting" is the idea that fracture of the leg must be treated by rest in bed, so that the bones may "knit."

It is for such reasons that our treatment of fractures, especially of the long bones, has been of the most conservative nature, and our hesitation has been so great to depart from the old lines. However, in selected cases this ambulatory method has given results good enough to encourage us to go on with it, and to attempt to define the limits within which it should be applied.—*Medical Record*, Aug. 13, 1898.

#### DIPHTHERIA AND ANTITOXIN.

In the *New York Medical Journal* of July 23, 1898, MORIARTY tells us that the dose of antitoxin is the most important factor we have to meet, after the decision as to its prompt and early use. Personally, the author uses a thousand units with an infant; with a child from two to five years of age he uses 2500 units, ranging from 1000 to 2500, according to the character and intensity of the case. If it were one of the severe laryngeal type in a child two years old he uses 2500 units; and in a child from seven to eight and upward he uses not less than 2500, and has in two instances used 3500. He is sure the best results follow a full initial dose. He has never used the enormous doses of 4000 or 6000 units as the initial dose, as is occasionally recommended. If such a quantity were required, he would use 3000, and in a few hours follow this with the full dose. He has often thought the second dose produced less disturbance than the first. In any of these cases, if there is not an improvement after ten hours, he uses a second dose; and if the case is a severe one, he makes the second dose the same as the first. In his own cases he has used strychnine, whiskey, tincture of muriate of iron, a highly nutritious diet, with peroxide of hydrogen for a gargle or spray full strength for the first twenty-four hours, or until the membrane has been acted on, when he diminishes the strength and lengthens the interval. He has seen such a goodly number of desperate cases benefited by the use of antitoxin even late in the disease (the fourth or fifth day) that he believes every patient with diphtheria, laryngeal or other, no matter how late or how severe, should have a full dose of antitoxin.

The author wishes to emphasize his judgment in the following conclusions:

- (a) Diphtheria antitoxin *per se* is harmless.
- (b) Diphtheria antitoxin is practically a specific in diphtheria.
- (c) Diphtheria antitoxin is the rational treatment for diphtheria.
- (d) Diphtheria antitoxin must be used early.
- (e) Diphtheria antitoxin must be used in full dose.
- (f) It is necessary to have a reliable product.
- (g) Intubation is an essential associate of antitoxin in laryngeal cases.
- (h) There is no case so far advanced that antitoxin should not be used.
- (i) We should not wait for the report of the bacteriologist, but use it promptly on clinical grounds.
- (j) It must not be the last resort, nor can it be of much service in small doses.

#### THE INDICATIONS FOR OPERATION IN RENAL TUBERCULOSIS.

PARK (*Journal of Cutaneous and Genito-Urinary Diseases*, August, 1898) states that when once the conclusion is reached that the kidney is the seat of a tuberculous lesion, the sooner that organ is removed the better, providing only and always that there be in the other kidney or elsewhere no lesion of a similar character which would serve as a contraindication.

It is possible only in exceptional instances to make the diagnosis so early that one can rely fully upon non-surgical measures, meaning thereby the use of drugs and perhaps tuberculin. It is also most exceptional to meet with a kidney where the lesion is so isolated that one can safely remove but a portion of the organ.

The question as to the general propriety of operation must be first passed upon; then the exact diagnosis should be made, if possible, as to whether one kidney is involved or both. If it can be clearly established that both organs are affected with this disease, the removal of one will be of little benefit, and often rather a detriment. We have then to determine whether there is any serious tubercular disease elsewhere; especially is this true of the lungs and other inaccessible regions of the body. It is not necessarily so true of lesions in parts which may be safely attacked, as, for instance, lymphatic nodes near the surface, the long bones, the joints, and the skin.

When it can be positively established that

there is also tubercular disease of the prostate, seminal vesicles, and perhaps of the testes, the operation is of doubtful propriety, though sometimes with regard to the latter we may apply the same rule as pertains to lesions of other inaccessible parts of the body. When the ovaries are diseased they may possibly be removed at the same time as the kidney; when other deep organs are involved the operation is most inexpedient. When the peritoneum is at fault we may bear in mind the advantage which accrues from opening this cavity, and perhaps may decide to remove the kidney by the peritoneal route.

Operations upon the kidney are of gravity just in proportion to the precariousness of the condition which necessitates them; they should always be so regarded and so represented. To remove the kidney ordinarily is easy and is not a tedious operation, but when it comes to the dissection and separation of the ureter, when its removal is indicated, the measure seriously prolongs the operation—sometimes so much so as to endanger life. What it is best to do, therefore, under these circumstances, should really be left to the decision of the surgeon at the time of the operation, rather than to be carried out upon any preconceived plan.

Partial nephrectomy is contraindicated in theory—although one must confess that it is sometimes apparently successful in practise—because the percentage of cases in which the kidney is the seat of a single or isolated lesion is exceedingly small as compared with that where the lesions are multiple and disseminated. There is certainly reason to think that after the early removal of a tuberculous kidney the progress of the infection to the rest of the genito-urinary tract must be at least delayed and is sometimes apparently checked. This is in accordance with the experience of a number of competent observers.

As regards the selection of the operation, the surgeon has the choice between the intraperitoneal and extraperitoneal routes. The intraperitoneal route will be selected principally only in the presence of certain specific indications; it will often be called for in the case of little children, this being the only method by which the enlarged kidney can be safely removed in such instances. Whether the operator shall go through the mesentery or the mesocolon is a matter of minor importance, and must be decided entirely according to the emplacement of the diseased organ.

Of the extraperitoneal methods, most operators now select the oblique in preference to the lumbar incision, and for reasons which are quite obvious. The beauty of the method with which König's name is now so commonly connected is the extent to which the incision can be carried; if the size of the mass requires it, it may be extended to the external border of the rectus muscle on the affected side. For ease and convenience in almost every respect it certainly takes precedence over every other method, save in the rare instances in which the kidney is easily shelled out after opening the abdomen. Cases occasionally occur in which it will be of advantage to perform the operation in two sittings.

---

*REMOVAL OF BILIARY CALCULI FROM  
THE COMMON DUCT BY THE  
DUODENAL ROUTE.*

MCBURNIE (*Annals of Surgery*, October, 1898) gives the history and treatment of a case suffering from biliary calculi. Eliza M., forty-four years of age, came under his care on the 12th of April, 1898. The diagnosis lay between calculus obstructing the main bile-duct and carcinoma, the existence of a calculus being favored, on account of the absence of cachexia and gastric symptoms.

Operation was done on the 15th of April, 1898. A vertical incision five inches long was made through the skin, beginning just below the ninth costo-chondral articulation on the right side, passing through the rectus muscle parallel to the course of its fibers, about two inches from the median line. The liver was at once noted to be much enlarged and congested. Firm adhesions existed between an atrophied gall-bladder and the duodenum. Palpation of the gall-bladder failed to detect the existence of calculus within; the cystic duct seemed to be in a normal condition. Examination of the common duct revealed no abnormality until its extreme lower end was palpated through the anterior wall of the duodenum. Here a firm, hard body, apparently about an inch in diameter, was readily felt. This body seemed to be located at a point corresponding to the lower end of the duct just before the latter opened into the duodenum. Adhesions were so strong, and the situation of the mass so low down and so far behind the duodenum, that its examination from the posterior aspect of the duodenum was hardly possible. It was evident that a biliary calculus formed the center of this mass.

The duodenum was incised vertically at the middle of its descending portion, the incision made being about one and a half inches long. The orifice of the common duct was found on the posterior wall of the descending portion of the duodenum, directly opposite the incision just referred to. A probe, introduced through this orifice, immediately came in contact with a calculus. Slight enlargement of the mouth of the duct with the scalpel permitted the end of the calculus to be seen. The finger being then passed behind the descending portion of the duodenum, the lower end of the common duct containing the calculus was easily pushed forward into the incision in the anterior wall of the gut, and a little additional pressure being made with the left hand, with the right the incised orifice of the duct was pushed back from the calculus, allowing the latter to at once escape into the intestine. A probe was then introduced, which passed freely up the common duct, but no other calculus was found. Bile flowed freely into the intestine as soon as the stone was removed. The wound in the duodenum was now closed by three rows of fine catgut sutures, the application of these sutures being very easy and complete. The surface of the intestine and the surrounding area of the abdominal cavity was then carefully washed with hot saline solution, and the wound in the abdominal wall was completely closed, in separate layers, with catgut sutures. The skin wound was closed with silk, a bit of thin rubber being introduced at the center to drain the subcutaneous cellular space.

The gall-stone removed was oval in shape, hard, dirty-brown in color, and measured three-quarters of an inch in one diameter and one-half inch in the other. No nausea followed the operation, and no pain. On the following day only sterile water was administered by the mouth, nutrient enemata being given per rectum every four hours. Two days after operation a large ordinary enema produced a natural movement of a light color. The wound healed in a perfectly aseptic manner, the discharges from the bowel rapidly recovered a normal appearance, and on the 1st of May the patient reported herself as feeling perfectly well. Five days after operation the temperature became normal, and has remained so ever since.

The operation just described was devised by the reporter some six years ago, while he was operating upon a patient who was in an extreme condition of debility, deeply bronzed

with bile pigment, and had suffered for many years from obstruction of the common duct. A year previous to his operation the diagnosis of carcinoma of the liver had been made by a prominent consultant of New York, and the advice was given that she be removed to her home, as she must inevitably die. At the end of the year, no especial change having occurred, her husband, who was a physician, brought her once more to New York, and it was then that the operation to which we have referred was done. On opening the abdomen the liver was found much enlarged and engorged, the gall-bladder atrophied, containing no calculi, moderate adhesions covering the cystic and common duct, which were, however, easily broken down, allowing of complete palpation of the entire bile track. With one finger behind the duodenum and another depressing its anterior surface a large, hard mass was readily discovered lying behind the center of the descending portion of the duodenum. This was clearly a calculus. McBurney at first made a somewhat prolonged effort to so raise the duodenum and bring the lower end of the common duct into view as to enable him to open the latter and extract the stone. He found that this was quite impossible, for he could neither bring the lower end of the common duct into view, nor could he expect to be able to suture it. It occurred to him that if he entered the duodenum through the anterior wall of its descending portion he should come at once to the point where the duct joined the intestine. He therefore made a vertical incision, about one and a half inches long, at the point referred to, and found the papilla which marked the entrance of the common duct directly opposite the incision. A probe was introduced without difficulty, which, after passing about half an inch upward through the duct, came in contact with a firmly impacted stone. The orifice of the duct was first slightly incised, then with the aid of forceps largely stretched, until it was possible without difficulty to dislodge the calculus and draw it down into the intestine. Large quantities of bile immediately flowed into the gut. The wound in the intestine was then sutured with three rows of silk. The parts that had been exposed were carefully cleansed and the abdominal wound sutured with catgut, leaving only a small orifice for drainage by means of a piece of iodoform gauze. The drainage material was removed at the end of two days, and although the superficial wound was somewhat slow in healing, the patient

made a complete recovery without fever or other abnormal sign of any kind. Her weight, which had been reduced to ninety pounds, within six months has returned to her normal standard of 180. Since that time the writer has frequently seen this patient, and she has remained in robust health up to the present date.

In all the author has performed this operation on six different occasions, the last one a very short time ago, and in no instance has the slightest delay in the healing of the wound in the intestine been noted. One patient, who had always suffered from an excessively irritable stomach, died after prolonged and uncontrollable vomiting. No sepsis or wound disturbance of any kind was found in this case.

It seems that this operation has a very legitimate place in gall-bladder surgery, and one which has not been sufficiently appreciated. Why it has not been more frequently resorted to by others McBurney does not understand, unless it is from the traditional fear, which dates back to a period long before intestinal surgery was understood, of opening and suturing a piece of gut. When a gall-stone lies in the common duct, at any point in the upper two-thirds of that passage, the approach to it through the wall of the duct is not difficult. In most cases, however, the management of the wound in the wall of the common duct is by no means simple, for although the wound may be left open and the space about it drained through the anterior abdominal wall with comparative safety, yet of course one would much prefer when it is possible to avoid long-continued drainage with its accompanying dangers. Suture of a wound in the common duct can occasionally be accomplished with comparative ease, more especially if the patient is thin and no adhesions exist to interfere with clean intraperitoneal work; but very frequently the complete suture of a wound in the common duct is exceedingly difficult, especially when the wall of the duct has become much thinned by distention, and successful suture may be quite impossible.

When a stone is situated at the extreme lower end of the passage, and when it cannot be dislodged to a place higher up in the duct, its removal without opening the intestine is a matter of great difficulty and not a little danger. Under such circumstances it seems that the removal of the stone through the intestine is clearly indicated, there being no possible objection to the method, except-

ing the fact that the intestine is necessarily incised. When one remembers, however, how much easier, on account of proximity, it is to suture the anterior wall of the duodenum than to suture the incised wall of the common duct, and when one remembers the rapidity and perfection with which properly sutured intestinal wounds heal, the choice of operation in suitable cases seems to lie clearly in favor of the method which the author has described. His conviction is that this operation has a much wider application than he has thus far given it, and his experience would lead him to prefer this plan for the removal of a calculus situated at almost any point from the termination of the cystic duct to the point of entrance of the common duct into the duodenum. He has found the orifice of the duct very easily dilatable, and it may be freely incised for at least half an inch with perfect safety. The operation is quicker, cleaner and safer than the operation which is usually done. It has also the advantage that, by the introduction of a probe, the bile-ducts can be examined for a long distance upward towards the liver, and also, the orifice of the duct having been dilated to a large extent, there is far less likelihood that overlooked fragments of gall-stone, granular material, or thick bile will be retained and give rise to further obstruction.

---

ON THE CAUSE AND MECHANICAL  
TREATMENT OF SUBLUXATION OF  
THE SEMILUNAR CARTILAGES  
OF THE KNEE-JOINT.

SHAFFER (*Annals of Surgery*, October, 1898) calls attention to the fact that "Hey's Internal Derangement of the Knee-joint," occurring as it does from trivial mishaps as well as from major injuries, and being a not infrequent accident, it seems strange that there should be any doubt as to its essential trouble so long ago as 1803. A further study of the subject in Allingham's treatise, "Internal Derangement of the Knee-joint," published in Wood's Medical and Surgical Monographs in 1890, will dispel all reasonable doubt in the matter. It may be profitable, however, to inquire into its exact mode of production, but the essential nature of the trouble is well understood.

From these and other sources, it may be assumed that the "internal derangement" described by Hey is occasioned by a varying degree of displacement—by even, in many cases, an imperceptible subluxation of one

of the semilunar cartilages. In brief, a visible or manually demonstrated existence of the subluxation is not always necessary. The trouble is so far "internal" that in many cases the ordinary physical signs of a dislocation are not to be observed or felt. The writer has seen several cases where the trouble was diagnosed as a "sprain," and he knows of two instances where the physical signs of the trouble were so inconspicuous that a diagnosis of "a hysterical joint" was made.

A prolonged study of many cases convinces the author that, aside from the generally accepted view that this subluxation occurs while the knee is flexed and the leg is rotated, there are other contributive causes which have not been carefully investigated—in short, that it is not the simple fact that rotation of the tibia occurs at the knee during flexion and extension of the joint, for these are normal movements, but rather that there is a delayed or hindered extension and rotation which permits this accident to occur. It would seem, from his studies, that this subluxation is not likely to occur, and he doubts if it ever does occur, except perhaps in cases of violent traumatism, while the quadriceps extensor muscle is relaxed.

Nor is the trouble ordinarily considered as one which belongs to orthopedic surgery. Especially since Allingham's time it has been regarded as being within the domain of the general surgeon, and so it is in its purely operative aspects. But, as with chronic diseases of the spine and joints, it has its conservative side, and if orthopedic surgeons can offer relief and cure by mechanical means, the general surgeon will welcome their efforts and aid them in their work.

It seems plain from cases the writer records that in order to prevent the recurrence of a subluxation of the semilunar cartilage, it is necessary to correct the undue ligamentous weakness of the joint, and to prevent an abnormal rotation of the tibia; in short, to give the knee and ankle antero-posterior motion only. Under these circumstances undue strain is taken off the quadriceps and the ligamentum patellæ, and under favorable conditions the latter, as well as the relaxed crucial ligaments, may shorten very materially in the course of a few months.

The object is to prevent every movement at the knee and ankle except antero-posterior motion—in short, to turn the knee into true hinge-joint, removing entirely the rotation of the tibia. The important part of the appara-

tus Shaffer employs, next to its simple hinge movement, is the joint at the knee, which is so arranged that it will stop the extension just at the point of comfort to the patient, and this point of comfort represents an absence of strain upon the knee-joint ligaments. This is very essential to the cure of the trouble, for experience proves that if the strain is taken from the ligaments they will shorten, and the "wabby" knee will gain stability and strength in a few months.

It is important that the center of the pad at the knee should be opposite the true center of motion (opposite the most prominent point on the internal condyle is near enough) at the knee, and that it should rest snugly against the condyle without undue pressure. The apparatus need not be made heavy, the principal strength being necessary in the rod which connects the knee with the ankle-piece. It is preferable to have this rod on the outside.

In many cases of Hey's joint there is an acquired, or perhaps congenital, lateral mobility of the knee-joint. This condition existing, the normal rotation of the tibia in flexion or extension of the knee is greatly increased.

In many cases, if not in all cases, there exists an elongated ligamentum patellæ, which so modifies the action of the quadriceps extensor muscle upon the tibia that the force of its contraction upon the tibia is modified or delayed in such a way that extension and rotation are not synchronously performed. And it seems more than probable that this condition forms an important factor in the production of the subluxation of the semilunar cartilage.

#### THE CORRECTION OF SPINAL DEFORMITY BY STAGES UNDER AN ANESTHETIC.

GIBNEY in the *Medical News* of September 24, 1898, places on record additional notes on some cases already reported by him. He sets forth his plan of treatment with the idea of disabusing the minds of his readers, as his own has been disabused, of certain erroneous impressions and certain dangers which have been suggested by writers, some of whom are simply critics. At the same time he states that he has no desire to give the impression that the operation itself is entirely free from danger. The patient, for instance, may take ether poorly, too much force may be employed at the first operation, the disease itself may

be located in a dangerous part of the spinal column, or the personal environment of the patient may be a contraindication; yet Gibney is convinced that with reasonable care, such as orthopedic surgeons are in the habit of employing in their work, the deformity may be corrected by repeating the procedure, say half a dozen times. Again, a certain amount of correction may be secured without the use of an anesthetic by frequent renewal of the plaster-of-Paris or whatever dressing may be employed. Especially is this desirable when one is not thoroughly conversant with the use of plaster of Paris. Even in the best of hands excoriations may sometimes occur, and excoriations occurring in cases like these under consideration necessarily bring discredit upon the treatment.

In England, where plaster has for a long time been tabooed, steel and iron appliances are employed, yet such appliances are generally managed or controlled by skilful men. On the Continent plaster of Paris, with an immense amount of cotton-battling, is wrapped about the body, and it does seem that the deformity is bound to recur where so much cotton is employed. The ideal dressing would, of course, be a skin-fitting plaster-of-Paris bandage secured accurately about the salient points, thus insuring a perfect fit. In this country most practitioners are reasonably familiar with the use of plaster, and take certain precautions that will guard against excoriation. It may be just as well to state that excoriations are not the worst things a patient can have. Even if a small ulcer is produced over the tip of the boss, or a long one at the side of it, there is no real harm done. The only trouble is we are obliged to discontinue the fixation, during which period the deformity will recur. In the writer's cases he has not seen fit to include the head in the dressing. He has employed piano felting on either side of the boss, over the iliac crests, along the free ribs where these protrude, and has bound the felting on with a cheese-cloth bandage after having secured the pads more firmly by means of a needle and thread. With such precautions he rarely finds an excoriation.

In reapplying plaster when an anesthetic is not employed, Gibney has been in the habit recently of hyperextending the column and the hips, thus securing a very decided recession of the deformity. At the time he began this work he was under the impression that the method had not been employed in the City of New York. He finds since, how-

ever, that while this is true, it had been employed in Chicago. The writer then records five cases illustrating the points he has mentioned above; these include all the cases of Pott's disease, while he follows with three cases of lateral curvature, in which latter cases results were not so good. Yet it is a slow process. One gains very little at each operation, and consequently gets discouraged. Inasmuch as the cases subjected to this procedure are extreme, as a rule, and inasmuch as the apparatus and exercises fail to effect any decidedly good results, the author feels that it is our duty to resort to almost any method which is attended by the minimum amount of danger.

There have been a certain number of bad results in reported cases from the other side of the water, but none on this side. It is well to bear in mind that any good thing can be abused. At the same time we should remember that the deformities which are now under discussion are most obstinate, and at times unyielding. The aim should be to break up these osseous adhesions and to render the column flexible. This being accomplished and care being taken to hold the spine in better position for a few months, this treatment can be followed by gymnastic methods with greater hope of success.

---

#### THE TREATMENT OF RACHITIC DEFORMITIES.

REGINALD H. SAYRE (*Pediatrics*, Aug. 15, 1898) recommends the following treatment in this condition:

The treatment should be adapted to the pathological condition which happens to be present at the time when the case comes under observation. As these bone changes usually take place slowly, and, except in acute cases, are not accompanied by much pain or disability, the fact that rickets is present may escape observation until a marked degree of deformity attracts the parents' attention; but careful inspection of children who are brought for examination will often detect the presence of rickets, and the institution of proper diet and mode of life will prevent incipient deformities from becoming marked.

Cases like this should not be left to themselves, with the information that they will "grow out of it," but should be helped in the growing out process by treatment directed to improving their nutrition and general vitality. Cod-liver oil is certainly of very great benefit,

and should be tried, except possibly in extremely hot weather. It is almost always well digested, especially when given in the form of an emulsion. There has been a great deal of discussion both for and against the use of phosphorus. Kassowitz, from his experiments on lower animals, concluded that in small doses, long continued, it was capable of decreasing the size of the blood-vessels in the bones, and as these are abnormally large in rickets, he in consequence used it in the treatment of this disease, as he claimed with great advantage. Other observers have followed in his footsteps, and claim also very beneficial results, while still others have not found as great benefit in their observation. The writer, personally, thinks that it has yielded decidedly good results in his hands, though in almost all instances the child's mode of life has been such that he has found it necessary to correct errors in diet at the same time, and therefore the improvement which he has noticed may not have been due to the phosphorus, although he believes it is responsible for part of it at least. The form in which he has administered it has been the elixir of phosphorus of the National Formulary, devised by Dr. Charles Rice, head of the drug department of Bellevue Hospital, which is as follows:

Spirit of phosphorus, f ʒ iij ʒ;  
Oil of star anise, ℥ xvj;  
Glycerin, f ʒ ix;  
Aromatic elixir, q. s. ad f ʒ xvj.

Each fluidrachm contains  $\frac{1}{16}$  grain of phosphorus.

The author finds that children of a year old can take  $\frac{1}{16}$  grain of phosphorus three times a day with no bad results, and in children somewhat older he has given  $\frac{1}{8}$  grain three times a day, with great benefit. These doses are much larger than are usually employed, but he has seen no bad effects from them.

Small children with rickets ought to be kept in the recumbent position and receive daily massage, as the soft tissues of their bodies are as much below the normal tonicity as are their bones. In many of these cases slight antero posterior or lateral curvatures of the spine can be detected, and in such cases Sayre knows of nothing so useful as the wire cuirass. It is far better than confinement in bed, as it permits the child to be carried outdoors for fresh air and sunshine—two great aids in cases of malnutrition, whose effect seems often to be overlooked, while too much importance is attached to drugs.

Curves in bones are often found even before children have walked, and manipulation by the hand is an excellent method of reducing these in slight cases. This sort of manipulation in the great majority of cases, however, can be practised but a short part of the twenty-four hours and must generally be supplemented by instrumental aid to retain the improved position that has been secured by the hand.

It is unusual for children with rickets to come under the observation of the orthopedist until they have begun to walk, when they are not infrequently brought to be cured of pigeon-toe; and upon examination it is discovered that the pigeon-toe is produced by the child's instinct, which teaches it to turn its toes in in order to avoid undue strain upon the arch of its foot, which the latter is incapable of sustaining on account of the debilitated condition of its bones, ligaments, and muscles; so that if we adjust an apparatus which compels the child to turn its toes out, we will be doing it vastly more harm than good, causing a flat foot to result, and quite likely increasing the tendency to knock-knee, which the child very probably presents. We will further find, upon questioning the parents, that the child has always perspired very freely around the head, possibly to such an extent as to leave a wet place upon the pillow, and that it continues to do so, while careful examination of its body will reveal the presence of abnormally large epiphyses, with a history that the child has been slow in walking.

If the case has advanced further, and a decided knock-knee or bow-leg is present, and it is found that the bone is at all springy, the author resorts to the use of a plaster-of-Paris bandage, extending from the toes as high as possible on the thigh, and bends the leg as nearly straight as possible while the plaster sets. If it has not been possible to wholly correct the deformity in this manner, after the expiration of a day or two, the author cuts through the plaster shell at the point of greatest deformity, and bending the leg toward a straight line, opens a gap at the point where he has divided the plaster. Into this gap a small plug of wood is inserted, and a few turns of the plaster bandage applied to unite the upper and lower parts of the splint.

In following out this treatment it is necessary to protect bony prominences from undue pressure, and not to correct the deformity to such an extent as to cause pain to the child

after the bandage has been applied, otherwise a pressure sore will be the probable result. After a week or ten days this process may be repeated until the legs have been brought to a normal position.

This method the writer believes was first introduced by Wolff, in Berlin, and has been in his hands infinitely more satisfactory than the application of braces and straps. In cases of children whose bones are sufficiently hard to make it wise to allow them to walk it is not practicable, as a usual thing, to apply a brace and strap to a bow-leg or knock-knee in such a manner as to exert force upon the bone sufficient to be of much benefit, and he has found this plaster dressing, which seems at first sight extremely clumsy and inconvenient, much cheaper and more effective, possessing the additional advantage for country practitioners that the services of a skilled mechanic are not required.

In some cases of lateral curvature the underlying cause of the deformity is evidently rickets. In such cases, in addition to exercise, gymnastic training, and diet, the spine should be supported by a plaster-of-Paris jacket, which should be worn until the soft stage of the disease has passed, irrespective of the time this may require.

In cases of knock-knee and bow-legs, where the deformity has been corrected either by manipulation or osteotomy, it is often advisable for the child to wear a slight supporting brace, for the purpose of preventing the return of the deformity, and to this end the author thinks that instruments with joints are as useful as he has found them useless in the correction of deformity.

If the patient has passed to the latter stage of the disease, and eburnation of the bones has taken place, it is useless to waste time in endeavors to rectify the deformity by manual or instrumental means, and the bone must be broken either by an osteoclast or a chisel. Which instrument should be used depends largely upon the preference of the surgeon, upon his skill in using either the one or the other, and partly in the location of the curve. Sayre states that he, personally, can divide a bone closer to the joint with a chisel than he can with an osteoclast, and should prefer osteotomy in cases where he wishes to make a section very close to a joint. But in cases where the bone is to be divided at a distance from the joint greater than two inches, he finds the osteoclast of Dr. Grattan, of Cork, a useful appliance, and in cases where he wishes to break the tibia and fibula in two

places, in order to correct the deformity, he prefers to use it. As originally introduced by Dr. Grattan, it had the disadvantage of requiring a very skilled assistant to study the pressure-bar of the instrument, in order to avoid cutting soft tissues; but this is avoided in his later apparatus by making the pressure-bar automatically controlled by means of a handle which passes through the base of the apparatus. The straight edge of the pressure-bar in both of Grattan's instruments renders it liable to cut the skin, and Dr. A. M. Phelps has modified the apparatus, curving this bar and making it less sharp, almost entirely removing the danger of lacerating the skin.

In the after-treatment of these cases, whether we employ osteotomy or the osteoclast, it is necessary that the splint employed should pass sufficiently far from the seat of fracture to retain absolute control of the fragments, as is true of all fractures, and in consequence it is always wise to run the splint well up upon the thorax in cases of knock-knee and high up on the thigh in cases of bow-legs, in order to hold the bones in such position as to correct the deformity. This is especially true in those cases of knock-knee in which there is a rotation of the femur on its long axis, as well as a hypertrophy of the inner condyle, so that when the neck of the femur is in its normal relation to the pelvis the foot points outward at right angles to the body instead of straight ahead. In these cases it is not only necessary to correct the angular deviation at the knee-joint, but to rotate the lower fragment of the femur upon the upper, sometimes as much as  $75^{\circ}$  or  $80^{\circ}$ , that the foot may be brought in proper relation to the body. In cases of bow-legs in very small children it is often a good plan to fasten the plaster-of-Paris shoes to a cross-bar, by means of which the legs of the child can be kept at right angles to its body by suspending them from a rod at one end of the bed, the chances of wetting the plaster being thus diminished.

The writer emphasizes, also, the possibility of non-union in some of these extremely rachitic cases, the bone seeming incapable of reunion, probably on account of the great eburnation which is present, which has impaired nutrition to an extent sufficient to prevent the formation of new bone cells. This emphasizes the importance of treating the case in the beginning, while the bones are sufficiently soft to be bent, rather than waiting until fracture of the bone becomes necessary.

*THE VALUE OF RECTAL LAVAGE AND IRRIGATION.*

RAMON GUITERAS publishes an exhaustive article on this subject in the *Post-Graduate* for August, 1898. He thinks that in rectal hydrotherapy by means of irrigations we have an extensive field for work and observation; that the best results are obtained in cases where there are distinct pathological lesions in the rectum or lower bowel; that the diseases of the genital tract, both in the male and in the female, are far more benefited by this treatment than is generally supposed; that the influence of these irrigations on the secretion of the kidney as shown is of the greatest importance, and should be tried in all cases where other means now in vogue have proved unsuccessful; that the effects of this procedure on the circulation seem to be so stimulating and so opposed to the conditions of shock that it would be advisable to employ it in cases of severe operation, where there have been or there is expected to be a considerable loss of blood, as a preventive measure.

*ANOTHER VIEW OF CONSERVATIVE SURGERY OF THE TUBES AND OVARIES.*

Cox (*Medical News*, Sept. 24, 1898) presents an exhaustive paper on this topic. He says the simplest form of conservative treatment consists in separating the adhesions around tubes and ovaries which present few if any macroscopic evidences of disease. This is, undoubtedly, a most valuable procedure, since these adhesions are often the cause of abdominal pains entirely out of proportion to the local lesion. The writer's experience is certainly not different from that of his readers when he says that, while many of these patients have been greatly benefited as regards the relief of both dysmenorrhea and persistent pains, the adhesions have often reformed. It is safe to say that up to the present time no method of absolutely preventing the reformation of such adhesions has yet been discovered. They occur after the simplest aseptic celiotomies; in fact, it is the rule to meet with them in secondary operations. Although he has practised the method frequently he has always regarded the mere separation of such adhesions by vaginal section as an operation of no permanent value, especially when the ovaries were prolapsed in Douglas' pouch. They naturally tend to resume their former position, and to become fixed by fresh adhesions. It has seemed to the author much more rational to employ the

abdominal route, and, after separating an adherent ovary, to suture it near the pelvic brim. Conception has undoubtedly followed this simple procedure, but one can instance quite as many cases in which the patient became pregnant with one or both ovaries buried in adhesions.

A further step in the direction of conservatism is the puncture or excision of small cysts on the surface of the ovary. This seems to carry us back to the early days, when we used to remove such ovaries simply on suspicion. Surely we have learned a little pathology since then: among other things, the fact that such cystic ovaries are rarely the forerunners of large cysto-adenomata, and that dropsical follicles the size of marbles may still contain healthy ova. Pozzi has written much on the subject of ignipuncture of sclerotic ovaries. But in spite of the amount of honest work which has been expended on the histology of the ovary, we are not yet in a position to define strictly the limits between normal and pathologic cirrhosis in the stroma. Doubtless in the hasty inspection at the operating-table corpora fibrosa are frequently mistaken for inflammatory thickening. This being the case, how do we know, when we puncture or excise a cyst, or an area of supposed cicatricial tissue in the ovary, that we are really doing the patient a service by removing a pathologic condition? That she becomes pregnant afterward is hardly a proof that the operation was a direct cause of pregnancy. Invest the procedure with high sounding terms as we may, it still remains an experimental attempt to remove what we only suspect may be a cause of future trouble. Curettement is usually performed as a preliminary step, so that in successful cases there must always be considerable doubt as to whether this or the abdominal operation was the true factor in overcoming sterility.

It has been assumed by those who have written on this subject that the risks in ovarian and tubal resection are practically *nil*, but the writer is personally cognizant of a case in the practise of an eminent surgeon in which secondary hemorrhage followed the excision of a follicular cyst *per vaginam*. It was necessary to open the patient's abdomen several hours after the operation in order to check the bleeding, and her escape from death was little short of miraculous. In the case of small purulent and dermoid cysts of the ovary, excision of the diseased portions and suture of the raw surfaces is certainly

not entirely free from danger, since one cannot be absolutely certain that septic foci are not left behind. Delanger, one of the enthusiastic followers of Pozzi, admits that it is practically impossible to remove all the diseased tissue, and that we can only hope to reduce it to a minimum. Pozzi's theory that the action of the cautery causes the absorption of sclerotic tissue is largely theoretical; in fact, he limits the application of this method to what he calls "microcystic degeneration, and diffuse or edematous oophoritis." Landau calls attention to the well known anatomic fact that atresia following gonorrheal salpingitis is really a conservative process of Nature, and asks, quite pertinently, why, then, we should open up such tubes and expose the patient to the risk of a fresh attack of perisalpingitis, or even of death from infection? It is an elementary fact that unless a bacteriologic examination is made during the progress of the operation we are not in a position to affirm with any degree of positiveness concerning the infectious character of the fluid contained within an occluded tube. Pozzi not only asserts that fatal cases of sepsis have been reported after resection of the tubes, but believes that the reason why more women do not die is presumably due to the fact that the distal ends of the tube again become agglutinated, or else are surrounded by fresh adhesions.

In the author's experience, which now includes more than thirty cases (nearly all within the past three years), the immediate ill effects of the operation have not been such as to prejudice him against it on the ground of the added risk. The question as to the subsequent condition of the patient is more important. In all the cases in which he has operated it has been for the purpose of relieving severe pain and dysmenorrhea, and removing adnexa which were hopelessly diseased, or were the seat of small neoplasms. Most of these patients have been kept under observation, and with some of them it has been necessary to perform a secondary operation. This experience has been supplemented by secondary celiotomies performed upon patients who had previously undergone conservative operations at the hands of other surgeons. Doubtless this experience is not an uncommon one. As regards relief of symptoms, the following have been noticed:

In several instances in which dense adhesions were separated, the tube and ovary on one side were removed, and on the opposite side were freed of adhesions and secured as

nearly as possible in their normal position; the results were not as satisfactory as could be wished. The adhesions evidently reformed, the patient suffered from practically the same pain as before, and but slight difference was noted as regards dysmenorrhea. In all these cases the convalescence was afebrile, no drainage was employed, and with few exceptions absorbable sutures and ligatures were used. An examination of several of these patients at intervals of from three to twelve months after operation showed the presence of a painful induration at the site of the remaining ovary and tube. In only one instance, thus far, has pregnancy occurred; this is now progressing normally, although the patient suffered from considerable local pain and menorrhagia for several months after the operation.

The variations in menstruation noted when a portion of the ovary, including from one-fourth to two-thirds of the normal stroma, was left behind have been many. In two instances menstruation, after returning slightly two or three times, ceased entirely. In other cases the flow was slight and irregular, but persistent; in two more profuse than before, and attended by pain several days before and during the flow. In the writer's experience the relief of dysmenorrhea has been gradual rather than immediate.

This result is hardly surprising in view of the fact that the portion of the ovary which remains has been known to atrophy entirely, or to undergo cystic degeneration. Cases in which a secondary operation has been necessary for the removal of a cystoma, developing from the remains of the stroma, or of a tubovarian cyst, have been reported by Martin and others. The author showed such a specimen at a recent meeting of the Obstetrical Society. Chrobak's objection, that there is great danger of ectopic pregnancy occurring in a resected tube, has fortunately proved to be a theoretical one so far as we are aware.

The first thing which women desire is to be relieved of the pain. When they do not find the promised relief, the question of conception becomes of secondary importance. In the case of young women who expect to be married, or of those who have been married only two or three years, this question assumes far more importance than with those who have been married for several years, or who have already borne one or more children. Here the principal object of the operation is, it is assumed, to relieve pain and to restore health.

The following conclusions are submitted:

1. Conservative operations on the adnexa are to be commended in properly selected cases. The surgeon should avoid, on the one hand, tampering with ovaries that are the seat of slight cystic degeneration or cirrhosis, and, on the other, trying to preserve supposed normal tissue in organs which show such extensive disease that it is doubtful whether the best interests of the patient (both immediate and remote) would not be served by complete removal. In many cases it is advisable to simply separate adhesions. As there is no way of preventing their reformation, it is better to suture prolapsed tubes and ovaries at their normal level in the pelvis.

2. In a certain proportion of cases resected ovaries undergo complete atrophy; in others the stromal remains may form the starting-point of cysts, requiring a second operation for their removal. A tube which has been rendered patent by dissection may again become occluded, or may form a hydrosalpinx or tubo-ovarian cyst.

These are often entirely satisfactory as regards the relief from pain and dysmenorrhea, the preservation of the functions of ovulation, and the occurrence of conception. *Per contra*, constant pain and dysmenorrhea may persist, menstruation may be absent, scanty, or excessive, and pregnancy is so far the exception that it is to be regarded as an unusually fortunate sequence. In any case, we are not in a position to affirm how far conception following resection of the adnexa is directly due to this procedure, or how far to the accompanying treatment—curettement, separation of adhesions, restoration of the general health, improved sexual relations, etc. Our main object is the avoidance of the premature climacteric.

As regards technique, experience has shown that more successful conservative work can be done by the abdominal route, for reasons that are obvious—*i.e.*, thorough separation of adhesions, suture of raw surfaces, checking of hemorrhage, avoidance of drainage, etc. Catgut is preferable as a suture material.

As a corollary to the above, emphasis should be laid on the fact that since the surgeon can never know the exact condition of the adnexa before opening the abdomen, he must not allow himself to be bound by any positive promise as to his course of procedure at the operating-table. While he should endeavor to preserve healthy organs and tissues whenever this is possible, and must necessarily be

guided to a considerable extent by the expressed wishes of the patient, he must not be persuaded against his better judgment to practise conservatism at the immediate risk of her life, or to court ultimate failure in order to give her the more than doubtful chance of future pregnancy.

The conscientious surgeon will not express himself too enthusiastically regarding the results of conservative operations for fear of arousing hopes which may be doomed to disappointment.

---

#### THE TREATMENT OF PROSTATIC HYPERTROPHY BY THE GALVANO-CAUTERY.

BOTTINI (*Centralblatt für die Krankheiten der Harn- und Sexual Organe*, Bd. ix, Heft 3, 1898) describes at length the treatment of prostatic hypertrophy with the galvano-cautery. Any surgeon who can pass a catheter is able to make the incision and cauterization by the galvanic instrument. The operation is in no way difficult. The bladder is first emptied; there is then injected into it through the urethra a one-per-cent. solution of cocaine. The surgeon waits for five minutes, and after repeated anesthetization of the urethra and neck of the bladder introduces the instrument, turns the cutting portion against the diseased part, sets the irrigating apparatus in motion, and turns on the electrical current until the knife is heated red-hot. Slowly and gradually the cut is made through the prostatic tissue to the extent deemed necessary to allow the urine to flow freely. After the completion of the operation, which requires two or three minutes, the current is turned off, but the circulation of the water is continued until the instrument has a chance to become cool. The operation is extraordinarily easy and is accomplished without drawing a drop of blood and without giving the patient the least pain. The therapeutic effect is noticed almost immediately; even after a few hours the patient urinates spontaneously.

Bottini has devised two instruments, which he calls the cauterizer and the incisor, having for their object the destruction by heat of a more or less extensive portion of the prostate without injury to the mucous membrane of the urethra and bladder. A stream of water is so arranged that it flows about the instrument, cooling all parts but that brought in contact with the prostatic tissue. The incisor is the instrument which he prefers.

ONE HUNDRED AND FOUR CASES OF  
CANCER OF THE UTERUS TREATED  
BY TOTAL EXTIRPATION.

THUMIN (*Berliner Klinische Wochenschrift*, Nos. 18 and 19, 1898) contributes the history of 104 cases of uterine cancer treated by total extirpation of the womb. There were eight post-operative deaths; thirty-eight died of recurrences; seven were lost to view, although it was known that recurrence had taken place. Two died of metastasis, and in fourteen the cause of death was unknown. Thirty-two remained free from recurrence (30.7 per cent.); thirteen of these were living more than five years after operation. Of the fourteen cases of carcinoma of the body of the uterus, ten were free from recurrence; three of the latter were under thirty years of age, and one had remained well nine years, and one six and a half years, after operation. This would seem to show that the prognosis of cancer in young women is not absolutely hopeless, though Thumin notes that the slow-growing cancers of old women are much more amenable to radical cure, since of ten such cases six remained well for periods varying from one to nine and a half years.

Among the cases which recurred it was noted that the average period of recurrence was a little over nine months; the average duration of life about seventeen months. The operations were completed in one period. In doubtful cases a portion of the growth was removed and examined, and if found malignant the surgeon proceeded immediately to operation. In two cases the paravesical tissues were involved and suture of the bladder was required. In both there was recurrence after operation, and in one case a ureteral fistula; twice there was secondary hemorrhage.

TO PALPATE AN APPENDIX.

An easy way is to stand on the patient's right, using three right-hand fingers to feel with, and three left-hand fingers placed upon these to press with. The fingers that are to do the feeling are pressed by means of the three others down under the border of the right-rectus abdominis muscle at the level of the navel, and slowly drawn toward the examiner. The author's sole landmark, the ascending colon, is then felt to slip out from under the fingers, and by repeating the process toward the cæcum we soon come to its end, and there begin to hunt for the appen-

dix by rolling the cæcum from one side to the other of the finger-tips. The proximal end of the appendix is found near the distal extremity of the cæcum, and we then follow the rest of the appendix in any direction. The proportion of appendices that cannot be palpated will become smaller and smaller as the finger-tips become educated. The point about using no muscular effort in the hand that is to be used in feeling is as important in palpating appendices as it is in palpating ovaries and tubes. The very delicate sense of touch is preserved if the left hand is used for pushing upon the examining hand.—*Medical Record*, Sept. 17, 1898.

THE RADICAL CURE OF CONGENITAL  
HYDROCELE.

Dr. MENCIERE (*Archives Cliniques de Bordeaux*) reports two cases of congenital hydrocele in which the following operative method was used with perfect satisfaction. The operation consists in making a long incision along the long axis of the tumor—that is to say, from above downward, the incision being prolonged to the inguinal ring. The serous membrane should be freely incised, as is done in the method of Volkmann. The peritoneo-vaginal canal should be destroyed by cutting transversely through it with the scissors. The edges of the serous sac thus formed should be brought together and sutured with catgut in such a way that the testicle will be contained in a reconstructed vaginalis, smaller than the first. Above this new vaginalis the serous membrane should be cut to a certain height, so that the peritoneo-vaginal canal will be destroyed beyond a doubt. Then, considering the superior part of this canal as a hernial sac, proceed with the radical cure of hernia. The inguinal ring is closed, the portion of the peritoneo-vaginal canal immediately beneath is destroyed—that is, excised; the testicle is contained in a new vaginalis smaller than the first, whose walls have been destroyed according to the method of Volkmann, the cavity not having ulteriorly any communication with the abdominal cavity. This method, differing from that described by Faure and from that which consists in simply practising a radical cure as in a hernia, is habitually employed. Here the author is not content with opening the vaginalis and reckoning on an adhesive inflammation to obliterate the peritoneo-vaginal canal. The surgeon should not only destroy

the canal, but should also close the inguinal ring. Again, instead of leaving the vaginalis to repair itself, as one does after operating for the radical cure of hernia, catgut sutures are employed to reconstruct it immediately. The operator can, with impunity, reconstruct the vaginalis and afterward close the inguinal ring; but in the case of congenital hydrocele accompanied by hernia it is preferable to close the inguinal ring first, as indicated, and then proceed to repair the vaginal cavity.—*Medical Record*, Sept. 17, 1898.

ON THE SEALING OF OPERATIVE  
WOUNDS ABOUT THE ABDOMEN.

In the *Medical Press and Circular* of August 31, 1898, BISHOP presents a paper under this title. He says it has always been noticed that after division of any tissues, and especially after the separation of those previously adherent through inflammatory changes, although all spouting or even evident vessels were closed by ligature, twisting, sponge pressure, or in any other way, fluid still continued to exude from the raw surfaces; such fluid was usually colored to some extent by blood, and when bacteriology was even faintly understood, was recognized as excellent culture material for the growth of micrococci. Any failure to avoid septic processes in the wound, or in the cavity where these raw surfaces existed, was attributed to the presence of this fluid, which, gradually accumulating and becoming stagnant in the closed wound or cavity, was supposed to decompose, and it was assumed that the accompanying poisonous material thereby resulted. And no one can doubt but that this was true. The practise adopted was, however, one-sided. Every attempt was made to remove this fluid. Chassaignac introduced his rubber drainage tube; Koeberle, one made of glass; and Macewen, tubes made of decalcified chicken bone. Counter openings were made in the most dependent parts so that the influence of gravity might be enlisted in the attempt to drain it away quickly. In the case of the abdomen all such fluids were believed to gravitate into the pelvis; in women, into Douglas' pouch. Presently it was found that so long as the tube remained, so long was there always some fluid to remove, and that if left too long even pus was found in it, even if none were previously present. So a rule arose that when the fluid was colorless and sweet the tube might be taken away. Some surgeons preferred to leave a rubber

tube when the glass was discarded, gradually, and day by day, shortening this, regardless of the fact that if their previous theories were true the shortened tube could not reach the remaining pool of stagnant fluid, and so at last it was abandoned to the same risks as those existing at first. But the glass drainage tube had several dangers of its own. Unless it were constantly moved, or rotated, omentum and even bowel wall was caught in the small openings at the lower end of the tube, not only plugging them and so preventing any flow towards the tube, but themselves becoming injured.

Taking one hundred cases each of similar pelvic inflammation, untoward results, including fatal and complicated cases, followed in twenty per cent. undrained, but in fifty-four per cent. of drained operations; suppuration of the abdominal wound existed in fourteen per cent. of undrained, in twenty-four per cent. of drained cases. Deaths were six per cent. in undrained, thirteen per cent. in drained. These statistics are taken from a *résumé* of 563 abdominal cases.

Nor should all these troubles be avoided, had the patient or surgeon heard the last of the drainage tube. There was yet another, and apparently an unavoidable, result, and that was subsequent ventral hernia. The muscles of the abdominal wall are so disposed that, when firmly united, their combined action compresses the abdominal contents towards the spine, but when once the central union is divided, each half tends to drag itself still farther from its fellow of the opposite side. If reunited at once, and kept together by sutures which will not yield until the plastic stage is over, and a firm fibrous union established, hernia does not appear to be probable, but if allowed to remain open at any one spot until granulation tissue is formed, the union is for a long time so soft and pliable that the action of the muscles slowly but surely thins it out, until a very little increase in the internal pressure of the abdominal cavity demonstrates the weak spot by a hernial protrusion.

The writer then inserts a case illustrating the point above stated. He says we may consider pus found in chronic pus sacs as practically free from active organisms, and as merely representing the débris left behind after the authors of it have perished. With regard to other fluids, Waterhouse's observations show the necessity for careful hemostasis, before the closure of the peritoneum, so as to avoid the possibility of including

blood clots of any size. The only other fluid likely to be present in the majority of cases will be the serous oozing from any large adhesion which has necessarily been separated during the operation. As far as possible such raw surfaces should be covered by adjacent peritoneum, which is attached so loosely that in most instances it can be drawn over them, and this fluid may safely be left to be dealt with by the peritoneum. It is of course evident that progress in this direction is absolutely dependent on the exclusion of germs, the maintenance of absolute asepsis.

There remain a very few exceptional cases in which great damage has been done to intestine, and in which it is impossible to feel certain that the bowel wall may not give way. As to these opinions are still greatly divided, and it seems at present impossible to lay down any definite rule—but these cases are rare.

The question of drainage of the abdominal cavity incidentally involves the question of general drainage of wounds, and it is easy to show that most of the arguments used in reference to the one apply with similar force to the other. In this relation, however, the treatment of the incision in the abdominal wall is of importance. If no drainage is required for the cavity, then no drainage is needed for the abdominal wound. We have, by its elimination, all the conditions favorable for primary union of the tissues composing that wall; and when once the whole line of incision is closed, and the edges of the skin approximated in a right line, it is evident that the second question arises to which we have referred as in process of change, and that is the one of dressings.

If we could at the moment when the operation is finished apply some air-tight material which would seal the wound from the entrance of anything from without, and which would remain air-tight until healing was complete, all nutrient fluids would be preserved for their legitimate purpose, bacteria would be absolutely excluded, and primary union might be reckoned upon.

The first attempt under this line of reasoning was made with collodion and a wisp of cotton wool, which was so arranged as to cover the wound and its surrounding skin for some distance. Good results were obtained by this, but perhaps a later material has on the whole shown itself more fitted for the work. The collodionized wool shuts off the line of incision from immediate observation.

With the new dressing—celloidin—a transparent, closely adherent film could be applied, which in addition to this advantage of transparency added another of strong contraction. This latter quality acted for good in two ways: it decreased the area of the scar, an immense addition for good in some instances, as in scars about the face, and it tended to contract the skin vessels immediately around the line of union, thus limiting the tendency to overfulness of those vessels after any traumatism.

Dr. Mackenzie has reported three cases treated in this way with success: an amputation of the breast, removal of a large lipoma from the gluteal region, and a strangulated hernia. To these the writer adds three out of a large number as illustrating its use in abdominal practice, typical of its advantage and at the same time of the advantage of the principle of non-drainage.

In all these cases, as in most in which this method has been used, the temperature rose during the first twenty-four hours; it did not go beyond 100°, and then steadily fell, not rising again.

Perhaps the last case emphasizes most thoroughly some of the advantages of the practice of sealing as opposed to the use of dressings. Children bear confinement badly, and its evil effects would have been greatly intensified had the use of drainage in this case necessitated the constant employment of dressings and bandages.

Of course, in order to avail oneself of these advantages, sterility during the precedent operation is doubly necessary. If, however, this is secured, the only other drawback that he has found to its use has been its tendency to produce small blisters at its edge. The celloidin plate, as it sets, contracts and drags upon the skin in all directions towards the line of union. Its edge frills, and just there small blisters will rise during the first two days. But if these are opened, the fluid dried off, and the surface dusted with boracic acid, so far he has seen no ill effect. If the blisters are not too large, they may indeed very safely be left. They gradually dry up, and when the whole covering becomes loose, as it tends to do between the tenth and the fifteenth day, being then only held by the sutures, the new epidermis has formed under the now dry scurfy material which represents the blister.

Even if the asepticity of one's work is not perfect, it is an advantage to be able to see at once through the transparent dressing

where it is faulty. Increased redness and heat are easily recognized, whilst the tension of increased swelling is quickly appreciated by the patient in its earliest stage, the celluloid being very resistant.

#### *TREATMENT OF TUBERCULOUS CYSTITIS BY INSUFFLATION OF STERILE AIR.*

REYMOND (*Ann. des Mal. des Org. Gén.-Urin.*, 1897, No. 8), led thereto by the excellent effects of laparotomy upon tuberculous peritonitis, has employed the insufflation of sterilized air in the treatment of vesical tuberculosis. Three cases were thus treated, all with benefit. In the first case there was marked amelioration of all symptoms after two insufflations. In the second one injection was followed by almost complete disappearance of the painful symptoms. In the third a permanent improvement was obtained after the third injection.

The method is pursued by means of a soft sterile catheter and syringe of about 100 cubic centimeters capacity. The air is filtered through a small wad of cotton placed in the nozzle of the syringe. One hundred cubic centimeters of air is driven in very gently and allowed to escape. Then twice or three times this amount is driven in rapidly and allowed to remain for five minutes, after which the catheter is suddenly withdrawn. The treatment is painless and should be repeated every second or third day.

#### *WOUND TREATMENT.*

RUTHERFORD MORISON gives the following summary of wound treatment in the *Medical Press and Circular* of August 31, 1898:

The antiseptic method, if contact of strong antiseptics with raw surfaces be avoided, allows of ideal wound healing.

In an uninfected wound no drainage is necessary.

For the arrest of hemorrhage, torsion should replace the ligature in the great majority of cases.

Buried catgut sutures are the best for securing apposition of the deeper structures and the skin, for by their use stitch abscesses and the pain and trouble of removing sutures may be avoided.

All clean wounds should be left undisturbed for ten days, and should then be healed.

## Reviews.

A TEXT-BOOK OF PHYSIOLOGY. Edited by E. A. Schäfer, LL.D., F.R.S. Volume I.  
Edinburgh and London: Young J. Pentland. New York: The Macmillan Company, 1898.

Here we have at last, in the English language, an exhaustive encyclopedic work upon Physiology, the chapters of which have been prepared by investigators who have devoted their lives to the study of the functions of the parts of which they write. In this respect the volume before us closely resembles the material which is to be found in Hermann's exhaustive work upon this subject, which so far as we know has never been translated into English, save, of course, that in the present volume physiology is described as it exists to-day, whereas Hermann's work deals with it as it existed twenty years ago. A feature of this volume, too, is the fact that copious bibliographical references are given in connection with every subject with which it deals, and while the illustrations are not as beautiful as some we are wont to find in other modern books, they are sufficiently good and sufficiently numerous to make the text of this the first volume clear and useful. Doubtless the second volume, which will deal with the functions of the nervous system and with the circulation of the blood and similar important topics, will be more profusely illustrated.

The chapters which make up Volume I deal with the chemical constituents of the body and food, with physiological chemistry, the blood, the lymph, the digestive processes, the urine, the milk, the function of the skin, the chemistry of respiration, animal heat, metabolism, and finally with the influence of the ductless glands upon metabolism, or in other words, internal secretions.

The book is one which the teacher of physiology cannot possibly do without, and is highly to be commended to physicians who are sufficiently anxious to make their methods rational to constantly bear in mind the fact that a thorough acquaintance with physiology is the *sine qua non* to professional success.

A TEXT-BOOK OF PATHOLOGY. By Alfred Stengel, M.D. Illustrated. Price, \$4.00.  
Philadelphia: W. B. Saunders, 1898.

Dr. Stengel tells us in his preface that he has endeavored to present the subject of pathology rather from its clinical than its laboratory aspects, and that he has avoided as far as possible questions about which controversies are being waged, except in the

case of the nervous system, where a certain amount of controversial information is necessary. The book consists of nineteen chapters. Of these the earlier ones deal with the etiology of disease and with diseases of nutrition and metabolism, with disturbances of the circulation and of the blood. The fifth chapter deals with regeneration and degeneration, and the sixth with retrogressive changes, while the seventh and eighth deal with bacteria and diseases caused by them, with animal parasites and the diseases which result from their being taken into the body. The second half of the book is devoted to Special Pathology and deals with the diseases which affect the various organs of the body. We are glad to see that Dr. Stengel advances the theory that fever may exercise a conservative influence (p. 43), as we believe that in many instances it is by no means as harmful a process as many have supposed it to be. Some of the definitions which are given are so concise and brief that one wonders after he has read them whether all of the information which should be given is contained in them, but if it is, so much the better. We are sorry to note that very few of the cuts are original, and the colored ones are taken from other publications invariably. As, however, these publications are exceedingly good, this is not a serious blemish, except that it detracts from the original character of the work, and he who writes a book to-day should use every endeavor to justify his contribution to medical literature by making his work distinctly characteristic. In the text Dr. Stengel has undoubtedly succeeded in this line.

Physicians as they get more and more busily engaged in practise are too apt to neglect books of this sort, partly from lack of interest and partly because they feel that the text is oftentimes too much divorced from practical medicine to be of value to them. This is certainly not the case with Dr. Stengel's volume. It is emphatically a very useful book for the student and also for the practitioner, and we look forward to keeping it close at hand for constant reference.

ESSENTIALS OF MATERIA MEDICA AND THERAPEUTICS.  
Fifth Edition. By Henry Morris, M.D.  
Philadelphia: W. B. Saunders, 1897.

Aside from all that may be said for or against books of this class (quiz compends) we pass over its pages to discover the real value of the contents, and we feel the more inclined to do so since the text deals with topics in touch with the objects of the GA-

ZETTE. Further than this, the author is frank enough to state that criticisms, both public and private, will be gladly received.

The drugs discussed are studied according to classes, and the classification is practically that of Wood, which is probably the best extant, although it is odd to find that opium is not included under the heading of "drugs which affect the body by influencing excretion and secretion." The advantages of classification are many and so are the objections.

As criticisms are asked for the following may be made: The definition of oleoresins on page 23 is not that usually given, to say the least. The statement that the time to use quinine in intermittent fever is in the sweating stage is contrary to our present knowledge. The statement about hydrastin is very crude, even if correct, and few will believe that iron is of value in epilepsy, nor is it usually taught that in anemia this drug should be given till the patient is suffering from headache, nausea, and flushing of the face. Hydrated magnesia is scarcely a purgative (p. 54); turpentine is not an antidote to phosphorus. The singular and plural are mixed on page 68. Under calcium chloride nothing is said of its use as an antihemorrhagic, and if any one believes that antipyrin is not irritating hypodermically let him try it. We do not believe that acetanilid is primarily a heart stimulant in toxic dose. The answer to the question, "How do hypnotics act?" is long and difficult to understand, and the assertion that opium depresses the cardiac motor ganglia needs indorsement. The catheterization of the patient in opium poisoning to prevent reabsorption of the drug is not half as important as repeated lavage of the stomach, which is not mentioned. We doubt whether the bromides cause sleep by producing cerebral anemia, or that they lower blood-pressure while contracting the blood-vessels; and, finally, the statement that no case of acute poisoning is on record is incorrect (see Wood's Therapeutics). We doubt if coca ought to be classed as an anodyne, for it is really a stimulant, and the teaching that death from chloroform is due primarily to cardiac paralysis is hardly correct. Whether death from ether is usually respiratory is a question, for it is as a result of the action of ether upon the lungs or kidneys that death commonly takes place. Strychnine is not all of it eliminated unchanged in the urine, nor is chloral, given hypodermically, a useful means of treating nux vomica poisoning. Nitroglycerin is not

the slowest of the nitrites, and nothing is said of the effect of the nitrites on the vagus. We do not believe that pilocarpine raises arterial tension in man, and we think the use of it in pulmonary edema is, to speak mildly, very dangerous. As this book is entitled the "Essentials of Therapeutics," it is important that it should be essentially correct, and these suggested corrections will improve the next edition.

THE PRINCIPLES AND PRACTISE OF HYDROTHERAPY.  
A Guide to the Application of Water in Disease. By  
Simon Baruch, M.D. Illustrated.  
New York: William Wood & Company, 1898.

This large octavo volume of 429 pages is Dr. Baruch's latest and best contribution to the subject of hydrotherapy, a subject with which Dr. Baruch's name, at least in this country, is closely associated. In the early portion of the volume we find chapters in which are discussed the physiological effects of water, the functions of the skin, and the physical properties of water, while in Chapter IV the effect of the various hydriatic applications upon the physiological functions of the body are described. With the fifth chapter we pass to a description of the various forms in which water can be used and the diseases to which it may be applied with advantage. Finally, the book closes in its twenty-seventh chapter with a historical epitome and a description of hydrotherapy in various countries. From time to time through its pages are illustrations showing how Dr. Baruch employs the various kinds of baths, and these illustrations add much to the practical utility of the volume. One thing which pleases us particularly is the fact that Dr. Baruch has cast aside empiricism as far as possible and devoted himself to the application of water in disease as governed by strictly rational and physiological ideas. We are also very much pleased to note that, unlike many persons who are enthusiastic in the use of any therapeutic procedure, his statements are well judged and he is not carried away by his enthusiasm. He admits that the routine application of the cold bath in typhoid fever is not absolutely essential, telling us that a properly applied wet pack is a useful and acceptable alternative in fevers under such circumstances. We are also pleased to note on pages 136 and 137 that the patient is to be lifted from his bed into the tub during an attack of typhoid rather than be allowed to move himself, and on page 138 there is an excellent illustration as to the method by which a

patient should be treated after he comes from the bath when suffering from this disease. In this connection we would call particular attention to the *résumé* of the methods which may be employed satisfactorily in the treatment of typhoid fever on page 269, and particularly important is the advice that in advanced and neglected typhoid the plunge bath is not as wise as are other methods.

As we have said before, the book is valuable not only because it tells us how to use water in the treatment of disease, but because the statements of the author are countered by correct views as to physiological and pathological processes.

THE CARE OF THE BABY. By J. P. Crozer Griffith, M.D. Second Edition, Revised.  
Philadelphia: W. B. Saunders, 1898.

Dr. Griffith has provided the profession with a book which they can with safety and advantage place in the hands of such of their patients as are young mothers, and although in some portions of the work it has seemed to us he has given almost too much medical information, he has, as a rule, avoided the mistakes which have been made by other writers, who have endeavored to present medical facts to the lay mind.

There are eleven chapters in the book. After the introduction the first chapter deals with the important subject of "Before the Baby Comes," and then with the baby and its growth, its toilet, its clothes and food, its sleep, its government, its care-takers, the rooms in which it lives; and, finally, there is a chapter upon the sick baby, which chapter makes up almost one-third of the book, and in which are discussed most of the ailments from which children suffer. In the appendix a large number of pages are taken up with a discussion of remedies for local use and with a consideration of food preparations to be employed during illness. A copious index completes the volume.

The opening words under the chapter devoted to the consideration of the sick baby show us that Dr. Griffith has endeavored to prevent home treatment, which is so often disastrous in its results. He tells us that the chapter is not designed to render the mother capable of "doctoring" her own children, inasmuch as in the treatment of the sick baby the experienced physician often has his hands full. With this advice the book may be considered, as we have stated in the beginning of this notice, a safe and good one for mothers.

A LABORATORY GUIDE IN URINALYSIS AND TOXICOLOGY. By A. T. Witthaus. Fourth Edition.  
New York: William Wood & Company, 1898.

Professor Witthaus has long been known as the author of a successful book designed to aid the student in acquiring the rudiments of chemistry. In the present edition the first point of interest which strikes us is the fact that he has apparently taken up with the newer form of spelling: thus sulphate is spelled sulfate; but that he is not consistent in the new method is shown by the fact that he speaks of phosphates and spells the word *phosphate*.

The volume deals with chemical manipulations, with reactions, with the analysis of urine and urinary calculi, and with the detection of the various poisons. It is distinctly designed as a manual and not as an exhaustive treatise, and ably fulfils the object for which it was written.

A POCKET FORMULARY FOR THE TREATMENT OF DISEASES OF CHILDREN. By Ludwig Freyberger, M.D., Vienna.  
London: The Rebman Publishing Company, 1898.

This is a little volume about the size of a visiting list, bound with a flexible cover, and designed to give the properties and doses of most of the remedies which are commonly employed in the treatment of the diseases of childhood. How useful it will be we do not know. Under the head of each drug (each drug being arranged alphabetically) we find its properties, its uses, its therapeutic doses, and usually the formula illustrating how it can be used. In other words, it differs but little from the ordinary prescribing manuals, except that it is devoted particularly to the maladies of childhood. So far as we have been able to discover the statements made are reliable (with the exception that castor oil should follow the use of male-fern, which is dangerous) even if limited in their value by reason of their briefness, and errors in dose or therapeutic advice are as a rule not manifest.

AN AMERICAN POCKET MEDICAL DICTIONARY. Edited by W. A. N. Dorland, A.M., M.D.  
Philadelphia: W. B. Saunders, 1898.

No sooner is one useful dictionary published than another steps into the field to challenge its success and to illustrate that even that which seems perfect to the uninitiated may by care be improved. This little volume is stated to contain the pronunciation and definition of no less than 26,000 terms used in medicine and kindred sciences, accompanied by sixty extensive tables dealing with such

subjects as aneurism, oils, weights and measures, reflexes, and the various forms of microorganisms. The medical student of to-day, therefore, has before him three small pocket medical dictionaries, about the size of the ordinary visiting list, from which he can "take his pick," and we may add that should he choose this one he will obtain a lexicon of value to him not only in his student days, but for many years after.

STUDENTS' HISTOLOGY. By Maurice N. Miller, M.D.  
Revised by Herbert U. Williams, M.D. Third Edition. Illustrated.  
New York: William Wood & Co., 1898.

Eleven years ago this useful manual of histology first appeared, the present third edition being revised by Dr. Williams, who has endeavored to bring it in every way in touch with modern histological investigations. It is well printed and the cuts are well executed, which is an important factor not only for the sake of clearness, but because in this volume they are very numerous, and if badly executed would simply occupy valuable space to no purpose. Directions are given for the use of the microscope, the preparation of tissues for microscopical examination, and then in Part II a description is given of the microscopical examination of the various tissues of the body, including cartilage, bone, muscular tissues, and the various organs. By the judicious use of various sized type the points in the text which require emphasis are readily picked out.

The book strikes us exceedingly favorably and deserves, in our opinion, increasing success.

THE TREATMENT OF SKIN CANCERS. By W. S. Gottheil, M.D.  
New York: International Journal of Surgery Co.

This little book of some fifty odd pages deals mainly with the recognition and treatment of skin cancer, particular stress being laid upon the caustic method as the one which experience has commended to the author. He holds that arsenic is the caustic *par excellence* in all cases of cutaneous carcinomata in which treatment with an agent of that kind is applicable, since it possesses a selective action, and is not hurtful to healthy tissue nor to the organism at large. Its use always should be preceded by curetting, and in extensive ulcerations a part of the lesion only—some three or four inches—should be treated at one time, not because of the danger of absorption, but to keep within bounds the pain and swelling. Marsden's paste is

the one preferred; this is made up of two parts of arsenic to one of powdered gum acacia. The paste should be made fresh and applied by spreading it upon a piece of rubber plaster.

Some illustrative cases are appended, only two of which were followed a sufficient length of time to justify the belief that the cure was permanent.

THE OFFICE TREATMENT OF HEMORRHOIDS, FISTULA, ETC., WITHOUT OPERATION. By Charles B. Kelsey, A.M., M.D.

New York: E. R. Pelton, 1898.

In this book are found three lectures by Kelsey, none of them entering into practical details. The first lecture has for its object the counteraction of the prevalent idea in the medical profession that hemorrhoids and fistula are to be cured only by operation. The method of curing them by operation is, however, not described. The second lecture proves that the rectal surgeon should be both a skilled gynecologist and a ready abdominal operator. The third lecture is an argument in favor of rectal resection in favorable cases.

The main purpose of the book is apparently to call the attention of the profession to the advisability of referring rectal cases to its author.

CONTRIBUTIONS TO ORTHOPÆDIC SURGERY. By A. Sydney Roberts, M.D., with a Brief Biographical Sketch by James K. Young, M.D.  
Philadelphia, 1898.

This collection, undertaken for private distribution and prepared by the editor as a debt of gratitude, recalls the clear common sense and mechanical talent which had Dr. Roberts lived would have placed him among the world's foremost orthopedists. The papers, though written more than ten years ago, are still modern and can be studied with profit. Dr. Young in his memoir has fittingly and generously eulogized Dr. Roberts.

TESTS AND STUDIES OF THE OCULAR MUSCLES. By Ernest E. Maddox, M.D., F.R.C.S. Ed.

Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent & Co., Lim.; Hirschfeld Bros., 82 High Holborn, 1898.

"The endeavor of this little work has been to cull, from the many tests for the ocular muscles scattered through ophthalmic literature, a selection of the best, to be interspersed with a few original ones, and with several studies of the ocular movements." This is the modest opening paragraph of the preface of this publication, which is admirable in every

respect. Ophthalmologists are already deeply indebted to Dr. Maddox for his tests to reveal the various phorias and for his book on the "Clinical Use of Prisms and the Decentering of Lenses." The present volume increases this indebtedness, and is a book that should be read, studied and used by every ophthalmologist, and indeed, as Dr. Maddox himself suggests, by physicians who are investigating the phenomena of nervous disease.

In order to gain some idea of the scope of the book, it may be stated that chapters I to VII are concerned with anatomical, physiological, and indirectly with optical, principles, while chapters VII to XII contain what may be described as the practical matter, and deal with strabismus, ocular paralyses, mnemonics for ocular paralyses, ophthalmoscopic corneal images and suppressed squints, the name which describes the various types of heterophoria or latent deviations. The book concludes with a chapter on latent torsion, the eye in darkness, and an appendix, in which some of the newer matter taken from Mr. Priestley Smith's Bowman Lecture for 1898 is incorporated.

A pleasing thing is Dr. Maddox's skill in analyzing the literature and the full and fair credit which he gives to American scientific investigation and ingenuity in this line of research, particularly to the work of Stevens, Savage, Risley, and Duane. The book contains more than one hundred illustrations, for the most part black and white cuts, which amply illustrate the text. The print is good and clear, and the book of convenient size and well bound.

G. E. de S.

DIE HEILPFLANZEN DER VERSCHIEDENEN VÖLKER UND ZEITEN. Ihre Anwendung Wesentlichen Bestandtheile und Geschichte. Ein Handbuch für Ärzte, Apotheker, Botaniker und Droguisten. Von Dr. Med. et Phil. Georg Dragendorff.

Stuttgart: Verlag von Ferdinand Enke, 1898.

Those who are familiar with the splendid work done by Professor Dragendorff, at one time professor at the University of Dorpat, in the realm of medical botany, will welcome this his last contribution to medical literature, and the welcome will be all the more heartfelt because the manuscript was completed but a short time before this distinguished investigator died. Like many German works it is divided into fasciculi which deal with the various botanical divisions of those drugs which are used in medicine and allied sciences. The synonyms, habitat and other information concerning the drugs are first given, and then the various modifications of the drugs are named.

Comparatively little information is given in regard to their therapeutic properties, but where the drug contains active medicinal ingredients these are also dealt with. It is therefore a book which is better suited to the work of pharmacists than of physicians, but to those who wish a complete monograph upon medical botany in the German language this series of fasciculi, which has now been completed by the publication of the fifth fasciculus, will prove interesting and valuable.

**MEDICAL NEWS VISITING LIST FOR 1899.**

Philadelphia and New York: Lea Brothers & Company, 1898.

The Medical News Visiting List has now been used for many years by a very large number of active practitioners, who have come to regard it as a necessary convenience for their practise. It contains in the first few pages a good deal of valuable information as to dosage and therapeutics, illustrations showing the portions of the body which should be incised for the ligation of arteries, and after that blank pages properly super-scribed for the records of cases and general memoranda for cash accounts and obstetric engagements. Lists varying from thirty to sixty patients a week are made up in this form. It deserves its success and will continue to be a popular manual or pocket book of records for daily use.

**PHYSICIAN'S VISITING LIST FOR 1899.**

Philadelphia: P. Blakiston, Son & Company, 1898.

This is the forty-eighth year of the publication of this list, and it goes without saying that its continued cordial reception by the medical profession shows that it meets their wants. Its pages are outlined for thirty patients a week, and its preliminary material consists in a carefully arranged dose list and in an abstract detailing the means of treating asphyxia and similar accidents. To those who have been accustomed to employ it we need not commend it. To those who have not seen it we can cordially indorse it.

**HISTOLOGY: NORMAL AND MORBID.** By Edward K. Dunham, Ph.B., M.D. Copiously Illustrated.

Philadelphia: Lea Brothers & Company, 1898.

This is at once the most satisfactory and complete book upon the microscopic examination of healthy and diseased tissues which can be found. It has been prepared by an author who knows the needs of medical students from long and well tried experience, and by one who being yet a young man is thoroughly in touch with all the most recent methods of microscopical study. An unusual

characteristic of the volume is the fact that a good many of the illustrations are original, which is a pleasing fact to discover after studying works in which the same cuts are utilized for the description of very different text. As may be imagined from its title, the first 250 pages deal with normal histology and 130 pages more deal with the morbid changes which are recognized under the microscope. The paper and binding are exceedingly good and well arranged for laboratory work or home study.

## Correspondence.

---

### LONDON LETTER.

By RAYMOND CRAWFURD, M.A. OXON., M.D., M.R.C.P.  
LOND.

To the October issue of the THERAPEUTIC GAZETTE we contributed some observations on the occurrence of erythematous rashes after enemata. Since this Dr. Still has read a paper on the subject at the Clinical Society of London based on twenty-six cases which had occurred at the Hospital for Sick Children, Great Ormond Street. Like ourselves he has succeeded in clearly establishing the causal relation of the enema to the rash by inducing repeated rashes on repetition of the enemata. He describes the characteristic eruption as appearing chiefly on the front of the knees, backs of the elbows, buttocks, and face. Occasionally the rash was scarlatiniform. He finds the interval between the enema and the first appearance of the rash to vary from twelve to twenty four hours—a much longer period than we suggested—and the duration from twenty-four to forty-eight hours, while constitutional disturbance was habitually absent. We cannot, however, agree with him as to the absence of sore throat and pyrexia. Dr. Still suggested rather happily that a certain number of the cases of so-called "surgical scarlatina" were the result of enemata given before operation; and the resemblance was still closer because of the undoubted occasional occurrence of desquamation after enemata. Dr. Still put forward three possible explanations of the vasomotor disturbance: (1) absorption of some toxic substance from the soap of the enema, possibly from the fats or the resins used (in our recent paper on the subject we alluded to some experiments with various soaps, which seemed *prima facie* to negative this theory); (2) absorption of some fecal

toxin, thrown into solution by the enema (the view we also support); and (3) a reflex effect on the vasomotor centers. This may or may not be, but until we know something of reflex action the hypothesis can hardly rank as an explanation.

Dr. Snow makes some original suggestions as to the treatment of cancer with lymph-gland juice. His proposition seems to run much as follows: The nuclear particles of epithelioma are carried by the lymph to the adjoining glands, which arrest them and so prevent a general blood contamination. Microscopically we often find the lymphatic glands enlarged by this form of irritation, and their structure altered, yet without the survival of any malignant protoplasm. *Ergo*, it must be the function of the lymph glands not only to arrest but actually to destroy the protoplasm of cancer. The resisting power of different groups of glands appears to be different, but in all cases the resistance tends eventually to be overpowered. Dr. Snow's therapeutic inference may best be given in his own words (*Lancet*, Oct. 15): "On the supposition that a natural secretion is the active agent, Messrs. Wanick Brothers have made for me an extract of fresh lymph-glands warranted to contain, as far as possible, the vital qualities of the living organ. I have administered this to sundry cases with apparent benefit and never with any bad symptom. A gentleman seen in July, 1897, going down hill very fast with advanced cancer of the stomach, and very unlikely to survive beyond November or December, had his life prolonged until last April. I hope later to furnish details. I have no facilities whatever for physiological research. The object of my letter is to appeal to some competent physiologist to take the matter up and test it in the laboratory. He would require to ascertain whether a secretion of the gland is, as I suppose, the active agent, or whether, on the other hand, the destruction is effected by a phagocytic action of the lymph cells. Medicine is learning more and more to seek its best weapons in the natural secretions of the body itself. The above principle tallies with the most recent lines of advance." We have no wish to discourage the suggested investigations, but the evidence from therapeutic results can hardly as yet be considered convincing.

At a recent meeting of the Clinical Society Mr. Pearce Gould showed a case of lupus of the whole face treated by thyroid colloid with the most striking results. In three

weeks from commencing the treatment the whole ulcerated surface had completely healed, and the scar tissue was undergoing transformation from a hard hidebound state into a soft pliable condition. Incidentally Dr. Pringle alluded to a series of cases treated by thyroid colloid; he was of opinion that the thyroid colloid was by far the most efficacious preparation of the thyroid gland that is now used medicinally. He was able to point to remarkable results in a considerable number of cases, but his experience of the after history led him to believe that the cure was seldom if ever permanent, as foci of lupoid tissue always remained behind to light up the disease afresh. It was not made quite clear whether Pearce Gould's was a true case of lupus granuloma, or whether it belonged rather to the category of scrofuloderma. Dermatologists seem agreed that the thyroid colloid, like the serum preparations, is much more efficacious in cases of scrofuloderma than in cases of true lupus granuloma.

In the course of the last few months the crude therapeutics of the Christian Scientists and of the Peculiar People have on several occasions been unpleasantly exhibited in the London police courts. The last case—that of Major Lester—has attracted special attention because of the high professional position of the patient. After his medical advisers had pronounced his case hopeless because of an advanced state of tubercular peritonitis, he and his family solicited the services of a worthy widow of the Christian Scientist persuasion. This lady duly commenced her treatment before she had seen her patient, and essayed to alleviate his sufferings—aye, and to cure his disease—not by any medicinal agencies, but by "taking up the right thought of the omnipotence and love of God." Suffice it to say that in a period of one month Major Lester died after much suffering, in spite of the attempt of Mrs. Grant to usurp the special power which Christ had. The jury who sat upon the case very rightly expressed their abhorrence at the so-called treatment of the deceased. It is difficult to see in what lies the Christianity, and wherein the science of this treatment, which is no treatment. In excuse for her action—she having had no experience of peritonitis—Mrs. Grant informed the jury that Jesus Christ never sent the sick to physicians. Is Mrs. Grant ignorant of the elementary facts of Christianity, or did she seek to cover herself from the penalties of the law by a wilful falsehood? Or knowing of the healing

miracles of Christ, does she hold that these were performed by some other power than that which she claims is delegated to herself by God?

Has bromide of strontium any advantage over other bromides in the treatment of epilepsy? Dr. Roche alleges that it has. Every physician will agree that it is less depressing than bromide of potassium, but so far as we are aware the potassium salt is seldom nowadays used alone and in large doses, but almost invariably in small doses and guarded by some tonic drug, such as *nux vomica* or *digitalis*. Dr. Roche has given as much as three drachms daily of the strontium salt without any unpleasant symptoms. This dosage is certainly far larger than could safely be administered in the case of the potassium salt. Dr. Roche's plan of campaign is as follows: He commences with half a drachm night and morning in some vegetable infusion; if the attacks persist, the drug is rapidly pushed to the extreme limit of individual tolerance. When there is any warning of an attack, the patient is to take thirty grains at once, and repeat it every hour if necessary. Dr. Roche has found threatened attacks constantly averted in this manner, and as the strontium salt is seemingly without any poisonous effects there is none of the danger that would attend a similar dosage of the potassium salt. Dr. Roche particularly inveighs against trust in small doses.

At the recent meeting of the British Medical Association Dr. Ewart advocated the alternating administration of drugs by rotation as a practical principle of treatment. The principle is on the lines of the rotation of crops by which the farmer not only rests but fertilizes his soil. Dr. Ewart has been led to adopt this principle of administration by such considerations as these: (1) That some drugs—and those are chiefly the stimulants and the sedatives—lose more and more of their effect the longer they are continued; (2) that other drugs, being slowly eliminated or distinctly cumulative, acquire through prolonged administration an increased activity, and in some instances a modified and sometimes a dangerous action; (3) that the most active dose, in the case of any stimulant or sedative, and in that of many tonics, is (putting aside summation of doses or of their effects) the first dose. On purely theoretical grounds there is beyond question much to be said for Dr. Ewart's suggestions, but who shall say that they can be brought within the sphere of

practical therapeutics; for when, further, Dr. Ewart contends that patients may often be placed with advantage under the joint influence of several drugs, one trembles at the array of bottles around the sick-bed. We fancy Dr. Ewart would find as the logical consequence of his treatment that each of his nurses would demand the services of an experienced bottleman. Dr. Ewart argues that as the first dose of a drug is often the most effective, that therefore it is desirable that every dose should be the first dose; and this end he would attain by increasing the intervals between the doses. But what of the patient during these intervals? There is one point in Dr. Ewart's remarks that will receive universal assent, "that the adoption of this method would supply an opening for almost unlimited ingenuity and judgment in varying the combination of drugs and the order and periodicity of their rotation, to suit the individual cases," or in other words, that treatment conducted on these lines would be an admirable school of mental calisthenics.

The tuberculosis crusade progresses apace. At present nothing substantial has been done beyond the preliminary arrangements, but even now considerable sums of money have been guaranteed by the laity. Yorkshire leads the way, and by the munificence of one or two county plutocrats will soon be in a way to have a sanatorium of its own. The choice of sites must needs be a question of vital importance, but as the sanatoria are for the most part to be wooden and readily portable, an initial mistake will not be irreparable. It is hoped that once established these sanatoria will be self-supporting from the contributions of the middle-class patients, for whom they are intended. We sincerely hope that their success may warrant State aid in providing similar sanatoria for the poor and destitute classes.

---

#### PARIS LETTER.

By A. R. TURNER, M.D. (PARIS).

---

It may be of interest to your readers to know what is the most recent treatment of diabetes as advocated by Dr. Albert Robin, the noted therapist in France. In the first place the patient should be subjected to the special diet recommended in diabetes. If after one week of diet the sugar in the urine has not completely disappeared, the use of drugs is indicated.

Antipyrin is of prime importance in the *first stage* of treatment, and should be administered as follows:

- ℞ Antipyrin, 0.75 to 1 gramme;  
Sodium bicarbonate, 0.50 to 0.75 gramme.  
For one powder; two to be taken daily.

At this stage, tonics, such as cod-liver oil and quinine wine, should be administered; and a mineral water, such as that of Vals, should be taken at meal-times.

Antipyrin should be given five days in succession, at the end of which time the urine is to be again examined. If the urine contains less sugar the *second stage* of treatment may now be entered upon. This stage of treatment consists in the following measures: Every day at the midday meal forty centigrammes of quinine sulphate should be administered. After six days of such treatment it may be ceased for four days, and once more resumed for a second period of six days. In the morning at breakfast and in the evening before dinner one of the following trochisci are to be taken:

- ℞ Arseniate of sodium, 2 to 3 milligrammes;  
Carbonate of lithium, 10 to 15 centigrammes;  
Codeine, 2 to 5 centigrammes;  
Theriacum, 25 centigrammes;  
Dry extract of cinchona, 40 centigrammes.

For one trochiscus. Make No. 30.

The cod-liver oil and cinchona wine are continued.

After two weeks of the second stage of treatment the urine is to be once more examined, and the *third stage* of treatment is to be taken up. This third stage involves the use of opium, belladonna, potassium bromide, alkaline waters, and valerian. Thus, during eight days the following pill is to be taken:

- ℞ Extract of belladonna, 5 milligrammes;  
Extract of opium, 1 centigramme;  
Extract of valerian, 10 centigrammes;  
Cinchona powder, q. s.

For one pill; make 50. Two pills daily at meal-times.

The cod-liver oil is no longer given, but cinchona wine should still be administered. In some cases from two to three grammes of potassium bromide daily may be given in the place of the preparations containing opium and belladonna.

If after the above treatment the urine still contains sugar, the first stage should once more be taken up.

In a recent lecture Dr. Robin spoke of the treatment of diabetic coma. After describing a case recently occurring in one of his wards, he declared this condition to

be generally fatal, but considered that it could be prevented by due foresight. It should be feared whenever the patient presents any gastric disturbance, dyspnea, cerebral excitement or apathy, and the urine on examination presents Gerhard's reaction, which consists in the following: If to the urine be added a certain amount of a perchloride of iron solution, which should be allowed to run slowly down the side of the glass, the reagent, in conditions where no coma is threatening, gathers in the bottom of the glass, and the urine remains of the same hue as previous to the addition of the perchloride of iron solution. In cases, however, in which diabetic coma is threatening the reagent assumes a deep red color like that of port wine. This change is due to the presence of acetyl-acetic acid. In such cases an energetic treatment should be undertaken, as follows:

1. The antidiabetic diet should be suppressed and only milk given.

2. The bowels should be opened in order to admit of the discharge of all excretory poisons. Sulphate of sodium, which is likewise diuretic, should be given: sulphate of sodium, 30 grammes.

3. In order to saturate the acids formed in the organism twenty grammes of bicarbonate of sodium are to be administered daily by the mouth.

4. The heart must be seen to; if the pulse is small, quick, irregular, the following can be employed:

- Powdered digitalis leaves, 60 centigrammes;  
Distilled water, 150 Cc.

Make an infusion. Add ergotin 4 grammes, and take a tablespoonful three times a day.

When on the contrary the pulse is slow, soft, and weak, subcutaneous injections of citrate of caffeine may be given, or a dose of three grammes of theobromine.

5. In order to help in the digestion of the milk a small spoonful of the following preparation is to be given before each cup of the former:

- ℞ Sulphate of strychnine, 2 centigrammes;  
Distilled water, 300 Cc.

And after each cup the following:

- ℞ Pepsin, 25 centigrammes;  
Malt extract, 10 centigrammes.

6. Should any lactic fermentation occur fluoride of ammonium may be administered. It destroys the fermentations due to micro-organisms without affecting the soluble ferments:

- ℞ Fluoride of ammonium, 50 centigrammes;  
Distilled water, 300 Cc.

A tablespoonful with each cup of milk.

7. Inject daily subcutaneously two doses of glycerophosphate of sodium.

8. Frictions of the entire body should be practised with the following liniment:

- ℞ Balsam of Fioraventi,  
Camphorated alcohol,  
Tincture of cinchona, of each 100 Cc.;  
Tincture of nux vomica, 25 Cc.;  
Essence of cloves, 2 Cc.

9. Finally, administer to the patient "torrents of oxygen," to use Dr. Robin's own expression.

At the Congress of Gynecology and Midwifery, held at Marseilles from October 8 to 13, Dr. Segond, whom some of our readers may have seen in the United States, read a paper on the treatment of ectopic gestation. A brief synopsis of it may not be without interest. Dr. Segond spoke a few words on the medical means that had been employed, such as tapping, strychnine, morphine, electricity, bleeding, and other archaic methods, to use an expression employed by Pozzi.

The celebrated accoucheur of the last century, Baudelocque, had already spoken of the importance of surgical methods, however dangerous they might seem to be. Dr. Segond went on to distinguish the various surgical methods to be put into practise according to circumstances, and he employed the classification adopted by Pozzi in his work on Gynecology. This classification is as follows: Cases of ectopic gestation of less than five months' duration, and cases of more than five months' duration. Either class may be divided into cases of normal gestation, and cases disturbed either by the death of the fetus or by some other complication.

In the first class, where ectopic gestation has lasted less than five months, one treatment is indicated—laparotomy, with removal of the Fallopian tube. Removal by anterior or posterior colpotomy has been successfully achieved in a certain number of cases, but laparotomy is certainly a better operation. In certain cases of incipient gestation the tube may be incised and replaced. Following are a certain number of special cases: When the fetal cyst is intraligamental or situated below the pelvic peritoneum laparotomy is still indicated, but some difficulty may be met with in the enucleation of the cyst and suprapubic drainage may be found necessary. If the cyst is comprised in the uterine horn, it is often possible to remove

the cyst completely without injuring the uterus, though in some cases it may be necessary to remove the uterus either partially or completely.

In tubo interstitial gestation vaginal hysterectomy is feasible, but as diagnosis is well-nigh impossible in such cases it is preferable to employ laparotomy. When there exists likewise fibroma or cancer of the uterus, complete hysterectomy is indicated; vaginal during the first three months, later on abdominal.

A special chapter should be devoted to the complications that may supervene, and chief among them is hemorrhage, from simple hemato-salpinx to complete peritoneal effusion, comprising as middle terms encysted hematocele and hematocele with successive hemorrhages.

In the first case, namely, hemato-salpinx with or without hemorrhage, constituting a tumor that may be removed, laparotomy with removal of the fetal cyst is indicated, and in most cases this should be completely done, though in some Martin has succeeded in opening the cyst and removing the effusion by the vagina.

A second group is formed by cases of suppurating or septic origin. In such cases simple vaginal incision should be performed when the purulent collection is easily found, and vaginal hysterectomy when the lesions exist on both sides, unless the gestation is too far advanced or the mass to be removed too voluminous. Under such conditions laparotomy is clearly the best operation.

When the gestation is advanced over five months, correct diagnosis is absolutely necessary, but this once established the treatment to be followed and the indications for operation are those of abdominal surgery for tumors.

The most important question here is not how one should operate, but when the operation is indicated. Up to seven months, when the fetus is alive, it is better not to wait, but to operate, and in such cases marsupialization and abandonment of the placenta in the abdomen are indicated. Of course, in case a partially or wholly detached placenta is found, with hemorrhage, complete extraction is necessary. From seven to nine months it is better to bide one's time and to wait for a distinct indication for operation. If the fetus is dead, it is better to wait and to remove the entire cyst. When the fetus has been long dead it may be removed by vaginal incision. In such cases the placenta should be removed as completely as possible.
